# Jump search

From Wikipedia, the free encyclopedia

In **computer science**, a **jump search** or **block search** refers to a **search algorithm** for **ordered lists**. It works by first checking all items  $L_{km}$  where  $k \in \mathbb{N}$  and  $m$  is the block size, until an item is found that is larger than the **search key**. To find the exact position of the search key in the list a **linear search** is performed on the **sublist**  $L_{[(k-1)m, km]}$ .

The optimal value of  $m$  is  $\sqrt{n}$ , where  $n$  is the length of the list  $L$ . Because both steps of the **algorithm** look at, at most,  $\sqrt{n}$  items the algorithm runs in  $O(\sqrt{n})$  time. This is better than a **linear search**, but worse than a **binary search**. The advantage over the latter is that a jump search only needs to jump backwards once, while a binary can jump backwards up to  $\log n$  times. This can be important if a jumping backwards takes significantly more time than jumping forward.

The algorithm can be modified by performing multiple levels of jump search on the sublists, before finally performing the **linear search**. For an  $k$ -level jump search the optimum block size  $m_l$  for the  $l^{\text{th}}$  level (counting from 1) is  $n^{(k-l)/k}$ . The modified algorithm will perform  $k$  backward jumps and runs in  $O(kn^{1/(k+1)})$  time.

## Implementation [\[edit\]](#)

**Algorithm** JumpSearch

Input: An ordered list  $L$ , its length  $n$  and a search key  $s$ .

Output: The position of  $s$  in  $L$ , or **nothing** if  $s$  is not in  $L$ .

```

a ← 0
b ← ⌊√n⌋

while Imin(b, n) - 1 < s do
    a ← b
    b ← b + ⌊√n⌋
    if a ≥ n then
        return nothing

while Ia < s do
    a ← a + 1
    if a = min(b, n)
        return nothing

if Ia = s then
    return a
else
    return nothing
```
