Buchberger's algorithm

From Wikipedia, the free encyclopedia

In computational [algebraic geometry](#) and computational [commutative algebra](#), **Buchberger's algorithm** is a method of transforming a given set of [generators](#) for a polynomial [ideal](#) into a [Gröbner basis](#) with respect to some [monomial order](#). It was invented by Austrian [mathematician](#) [Bruno Buchberger](#). One can view it as a generalization of the [Euclidean algorithm](#) for univariate [GCD](#) computation and of [Gaussian elimination](#) for [linear systems](#).

A crude version of this algorithm to find a basis for an ideal *I* of a polynomial ring *R* proceeds as follows:

Input A set of polynomials *F* that generates *I*

Output A [Gröbner basis](#) *G* for *I*

1. $G := F$
2. For every f_i, f_j in *G*, denote by g_i the leading term of f_i with respect to the given ordering, and by a_{ij} the [least common multiple](#) of g_i and g_j .
3. Choose two polynomials in *G* and let $S_{ij} = (a_{ij} / g_i) f_i - (a_{ij} / g_j) f_j$ (*Note that the leading terms here will cancel by construction*).
4. Reduce S_{ij} , with the [multivariate division algorithm](#) relative to the set *G* until the result is not further reducible. If the result is non-zero, add it to *G*.
5. Repeat steps 1-4 until all possible pairs are considered, including those involving the new polynomials added in step 4.
6. Output *G*

The polynomial S_{ij} is commonly referred to as the S-polynomial, where *S* refers to *subtraction* (Buchberger) or *Syzygy* (others). The pair of polynomials with which it is associated is commonly referred to as [critical pair](#).

There are numerous ways to improve this algorithm beyond what has been stated above. For example, one could reduce all the new elements of *F* relative to each other before adding them. If the leading terms of f_i and f_j share no variables in common, then S_{ij} will *always* reduce to 0 (if we use only f_i and f_j for reduction), so we needn't calculate it at all.

The algorithm terminates because it is consistently increasing the size of the monomial ideal generated by the leading terms of our set *F*, and [Dickson's lemma](#) (or the [Hilbert basis theorem](#)) guarantees that any such ascending chain must eventually become constant.

The [computational complexity](#) of Buchberger's algorithm is very difficult to estimate, because of the number of choices that may dramatically change the computation time. Nevertheless, T. W. Dubé has been proved^[1] that the degrees of the elements of a reduced Gröbner basis are always bounded by

$$2 \left(\frac{d^2}{2} + d \right)^{2^n - 1},$$

where *n* is the number of variables, and *d* the maximal [total degree](#) of the input polynomials. This allows, in theory, to use [linear algebra](#) over the [vector space](#) of the polynomials of degree bounded by this value, for getting an algorithm of complexity $d^{2^n + o(1)}$.

On the other hand, there are examples^[2] where the Gröbner basis contains elements of degree

$$d^{2^{\Omega(n)}},$$

and above upper bound of complexity is almost optimal, up to a constant factor in the second exponent). Nevertheless, such examples are extremely rare.

Since its discovery, many variants of Buchberger's have been introduced to improve its efficiency. [Faugère's F4](#) and [F5 algorithms](#) are presently the most efficient algorithms for computing Gröbner bases, and allow to compute routinely Gröbner bases consisting of several hundreds of polynomials, having each several hundreds of terms and coefficients of several hundreds of digits.
