# Merge sort

From Wikipedia, the free encyclopedia

In [computer science](#), **merge sort** (also commonly spelled **mergesort**) is an  $O(n \log n)$  [comparison-based sorting algorithm](#). Most implementations produce a [stable sort](#), which means that the implementation preserves the input order of equal elements in the sorted output. Mergesort is a [divide and conquer algorithm](#) that was invented by [John von Neumann](#) in 1945.<sup>[1]</sup> A detailed description and analysis of bottom-up mergesort appeared in a report by [Goldstine](#) and Neumann as early as 1948.<sup>[2]</sup>

## Merge sort

6 5 3 1 8 7 2 4

An example of merge sort. First divide the list into the smallest unit (1 element), then compare each element with the adjacent list to sort and merge the two adjacent lists. Finally all the elements are sorted and merged.

<b>Class</b>	<a href="#">Sorting algorithm</a>
<b>Data structure</b>	<a href="#">Array</a>
<b>Worst case performance</b>	$O(n \log n)$
<b>Best case performance</b>	$O(n \log n)$ typical, $O(n)$ natural variant
<b>Average case performance</b>	$O(n \log n)$
<b>Worst case space complexity</b>	$O(n)$ total, $O(n)$ auxiliary

## Algorithm [\[edit\]](#)

Conceptually, a merge sort works as follows:

- Divide the unsorted list into  $n$  sublists, each containing 1 element (a list of 1 element is considered sorted).
- Repeatedly [merge](#) sublists to produce new sorted sublists until there is only 1 sublist remaining. This will be the sorted list.

## Top-down implementation [\[edit\]](#)

Example C-like code using indices for top down merge sort algorithm that recursively splits the list (called *runs* in this example) into sublists until sublist size is 1, then merges those sublists to produce a sorted list. The copy back step could be avoided if the recursion alternated between two functions so that the direction of the merge corresponds with the level of recursion.

Merge sort animation. The sorted elements are represented by dots. 

```
/* array A[] has the items to sort; array B[] is a work array */
TopDownMergeSort (A[], B[], n)
{
    TopDownSplitMerge (A, 0, n, B);
}

// iBegin is inclusive; iEnd is exclusive (A[iEnd] is not in the set)
TopDownSplitMerge (A[], iBegin, iEnd, B[])
{
    if (iEnd - iBegin < 2)                // if run size == 1
        return;                          // consider it sorted
}
```

[Suomi](#)[ไทย](#)[Türkçe](#)[Українська](#)[Tiếng Việt](#)[中文](#)[Edit links](#)

```
// recursively split runs into two halves until run size == 1,
// then merge them and return back up the call chain
iMiddle = (iEnd + iBegin) / 2;           // iMiddle = mid point
TopDownSplitMerge(A, iBegin, iMiddle, B); // split / merge left half
TopDownSplitMerge(A, iMiddle, iEnd, B);  // split / merge right half
TopDownMerge(A, iBegin, iMiddle, iEnd, B); // merge the two half runs
CopyArray(B, iBegin, iEnd, A);           // copy the merged runs back to A
}

// left half is A[iBegin :iMiddle-1]
// right half is A[iMiddle:iEnd-1 ]
TopDownMerge(A[], iBegin, iMiddle, iEnd, B[])
{
    i0 = iBegin, i1 = iMiddle;

    // While there are elements in the left or right runs
    for (j = iBegin; j < iEnd; j++) {
        // If left run head exists and is <= existing right run head.
        if (i0 < iMiddle && (i1 >= iEnd || A[i0] <= A[i1])) {
            B[j] = A[i0];
            i0 = i0 + 1;
        } else {
            B[j] = A[i1];
            i1 = i1 + 1;
        }
    }
}

CopyArray(B[], iBegin, iEnd, A[])
{
    for(k = iBegin; k < iEnd; k++)
        A[k] = B[k];
}
```

## Bottom-up implementation [\[edit\]](#)

Example C like code using indices for bottom up merge sort algorithm which treats the list as an array of  $n$  sublists (called *runs* in this example) of size 1, and iteratively merges sub-lists back and forth between two buffers:

```
void BottomUpMerge(A[], iLeft, iRight, iEnd, B[])
{
    i0 = iLeft;
    i1 = iRight;
    j;

    /* While there are elements in the left or right runs */
    for (j = iLeft; j < iEnd; j++)
    {
        /* If left run head exists and is <= existing right run head */
        if (i0 < iRight && (i1 >= iEnd || A[i0] <= A[i1]))
        {
            B[j] = A[i0];
            i0 = i0 + 1;
        }
        else
        {
            B[j] = A[i1];
            i1 = i1 + 1;
        }
    }
}

void CopyArray(B[], A[], n)
{
    for(i = 0; i < n; i++)
        A[i] = B[i];
}

/* array A[] has the items to sort; array B[] is a work array */
```

```

void BottomUpSort(A[], B[], n)
{
    /* Each 1-element run in A is already "sorted". */
    /* Make successively longer sorted runs of length 2, 4, 8, 16... until whole array
    is sorted. */
    for (width = 1; width < n; width = 2 * width)
    {
        /* Array A is full of runs of length width. */
        for (i = 0; i < n; i = i + 2 * width)
        {
            /* Merge two runs: A[i:i+width-1] and A[i+width:i+2*width-1] to B[] */
            /* or copy A[i:n-1] to B[] ( if(i+width >= n) ) */
            BottomUpMerge(A, i, min(i+width, n), min(i+2*width, n), B);
        }
        /* Now work array B is full of runs of length 2*width. */
        /* Copy array B to array A for next iteration. */
        /* A more efficient implementation would swap the roles of A and B */
        CopyArray(B, A, n);
        /* Now array A is full of runs of length 2*width. */
    }
}

```

### Top-down implementation using lists [\[edit\]](#)

**Pseudocode** for top down merge sort algorithm which recursively divides the input list into smaller sublists until the sublists are trivially sorted, and then merges the sublists while returning up the call chain.

```

function merge_sort(list m)
    // Base case. A list of zero or one elements is sorted, by definition.
    if length(m) <= 1
        return m

    // Recursive case. First, *divide* the list into equal-sized sublists.
    var list left, right
    var integer middle = length(m) / 2
    for each x in m before middle
        add x to left
    for each x in m after or equal middle
        add x to right

    // Recursively sort both sublists
    left = merge_sort(left)
    right = merge_sort(right)

    // Then merge the now-sorted sublists.
    return merge(left, right)

```

In this example, the `merge` function merges the left and right sublists.

```

function merge(left, right)
    var list result
    while notempty(left) and notempty(right)
        if first(left) <= first(right)
            append first(left) to result
            left = rest(left)
        else
            append first(right) to result
            right = rest(right)
    // either left or right may have elements left
    while notempty(left)
        append first(left) to result
        left = rest(left)
    while notempty(right)
        append first(right) to result
        right = rest(right)
    return result

```

## Natural merge sort [\[edit\]](#)

A natural merge sort is similar to a bottom up merge sort except that any naturally occurring runs (sorted sequences) in the input are exploited. In the bottom up merge sort, the starting point assumes each run is one item long. In practice, random input data will have many short runs that just happen to be sorted. In the typical case, the natural merge sort may not need as many passes because there are fewer runs to merge. In the best case, the input is already sorted (i.e., is one run), so the natural merge sort need only make one pass through the data. Example:

```
Start      : 3--4--2--1--7--5--8--9--0--6
Select runs: 3--4  2  1--7  5--8--9  0--6
Merge      : 2--3--4  1--5--7--8--9  0--6
Merge      : 1--2--3--4--5--7--8--9  0--6
Merge      : 0--1--2--3--4--5--6--7--8--9
```

**Tournament replacement selection sorts** are used to gather the initial runs for external sorting algorithms.

## Analysis [\[edit\]](#)

In sorting  $n$  objects, merge sort has an **average** and **worst-case performance** of  $O(n \log n)$ . If the running time of merge sort for a list of length  $n$  is  $T(n)$ , then the recurrence  $T(n) = 2T(n/2) + n$  follows from the definition of the algorithm (apply the algorithm to two lists of half the size of the original list, and add the  $n$  steps taken to merge the resulting two lists). The closed form follows from the **master theorem**.

In the worst case, the number of comparisons merge sort makes is equal to or slightly smaller than  $(n \lceil \lg n \rceil - 2^{\lceil \lg n \rceil} + 1)$ , which is between  $(n \lg n - n + 1)$  and  $(n \lg n + n + O(\lg n))$ .<sup>[3]</sup>

For large  $n$  and a randomly ordered input list, merge sort's expected (average) number of comparisons approaches  $\alpha \cdot n$  fewer than the worst case where

$$\alpha = -1 + \sum_{k=0}^{\infty} \frac{1}{2^k + 1} \approx 0.2645.$$

In the *worst* case, merge sort does about 39% fewer comparisons than **quicksort** does in the *average* case. In terms of moves, merge sort's worst case complexity is  $O(n \log n)$ —the same complexity as quicksort's best case, and merge sort's best case takes about half as many iterations as the worst case.<sup>[citation needed]</sup>

Merge sort is more efficient than quicksort for some types of lists if the data to be sorted can only be efficiently accessed sequentially, and is thus popular in languages such as **Lisp**, where sequentially accessed data structures are very common. Unlike some (efficient) implementations of quicksort, merge sort is a stable sort.

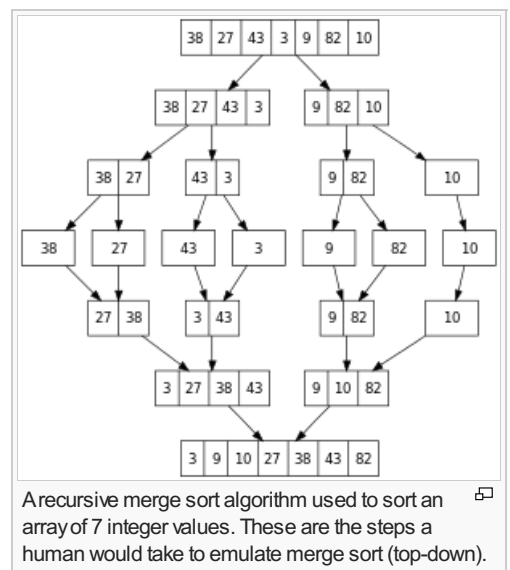

Merge sort's most common implementation does not sort in place<sup>[citation needed]</sup>; therefore, the memory size of the input must be allocated for the sorted output to be stored in (see below for versions that need only  $n/2$  extra spaces).

Merge sort also has some demerits. One is its use of  $2n$  locations; the additional  $n$  locations are commonly used because merging two sorted sets in place is more complicated and would need more comparisons and move operations. But despite the use of this space the algorithm still does a lot of work: The contents of  $m$  are first copied into *left* and *right* and later into the list *result* on each invocation of *merge\_sort* (variable names according to the pseudocode above).

## Variants [\[edit\]](#)

Variants of merge sort are primarily concerned with reducing the space complexity and the cost of copying.

A simple alternative for reducing the space overhead to  $n/2$  is to maintain *left* and *right* as a combined structure, copy only the *left* part of  $m$  into temporary space, and to direct the *merge* routine to place the merged output into  $m$ . With this version it is better to allocate the temporary space outside the *merge* routine, so that only one allocation is needed. The excessive copying mentioned previously is also mitigated, since the last pair of lines

before the *return result* statement (function *merge* in the pseudo code above) become superfluous.

One drawback of merge sort, when implemented on arrays, is its  $O(n)$  working memory requirement. Several [in-place](#) variants have been suggested:

- Katajainen *et al.* present an algorithm that requires a constant amount of working memory: enough storage space to hold one element of the input array, and additional space to hold  $O(1)$  pointers into the input array. They achieve an  $O(n \log n)$  time bound with small constants, but their algorithm is not stable.<sup>[4]</sup>
- Several attempts have been made at producing an *in-place merge* algorithm that can be combined with a standard (top-down or bottom-up) merge sort to produce an in-place merge sort. In this case, the notion of "in-place" can be relaxed to mean "taking logarithmic stack space", because standard merge sort requires that amount of space for its own stack usage. It was shown by Geffert *et al.* that in-place, stable merging is possible in  $O(n \log n)$  time using a constant amount of scratch space, but their algorithm is complicated and has high constant factors: merging arrays of length  $n$  and  $m$  can take  $5n + 12m + o(m)$  moves.<sup>[5]</sup> Other in-place algorithms include SymMerge, which takes  $O((n + m) \log(n + m))$  time in total.<sup>[6]</sup> Plugging such an algorithm into merge sort increases its complexity to the non-linearithmic, but still [quasilinear](#),  $O(n \log^2 n)$ .

An alternative to reduce the copying into multiple lists is to associate a new field of information with each key (the elements in  $m$  are called keys). This field will be used to link the keys and any associated information together in a sorted list (a key and its related information is called a record). Then the merging of the sorted lists proceeds by changing the link values; no records need to be moved at all. A field which contains only a link will generally be smaller than an entire record so less space will also be used. This is a standard sorting technique, not restricted to merge sort.

A variant named *binary merge sort* uses a *binary insertion sort* to sort groups of 32 elements, followed by a final sort using merge sort. It combines the speed of [insertion sort](#) on small data sets with the speed of merge sort on large data sets.<sup>[7]</sup>

## Use with tape drives [\[edit\]](#)

An [external](#) merge sort is practical to run using [disk](#) or [tape](#) drives when the data to be sorted is too large to fit into [memory](#). [External sorting](#) explains how merge sort is implemented with disk drives. A typical tape drive sort uses four tape drives. All I/O is sequential (except for rewinds at the end of each pass). A minimal implementation can get by with just 2 record buffers and a few program variables.

Naming the four tape drives as A, B, C, D, with the original data on A, and using only 2 record buffers, the algorithm is similar to [Bottom-up implementation](#), using pairs of tape drives instead of arrays in memory.

The basic algorithm can be described as follows:

1. Merge pairs of records from A; writing two-record sublists alternately to C and D.
2. Merge two-record sublists from C and D into four-record sublists; writing these alternately to A and B.
3. Merge four-record sublists from A and B into eight-record sublists; writing these alternately to C and D
4. Repeat until you have one list containing all the data, sorted --- in  $\log_2(n)$  passes.

Instead of starting with very short runs, usually a [hybrid algorithm](#) is used, where the initial pass will read many records into memory, do an internal sort to create a long run, and then distribute those long runs onto the output set. The step avoids many early passes. For example, an internal sort of 1024 records will save 9 passes. The internal sort is often large because it has such a benefit. In fact, there are techniques that can make the initial runs longer than the available internal memory.<sup>[8]</sup>

A more sophisticated merge sort that optimizes tape (and disk) drive usage is the [polyphase merge sort](#).

## Optimizing merge sort [\[edit\]](#)

On modern computers, [locality of reference](#) can be of paramount importance in [software optimization](#), because multilevel [memory hierarchies](#) are used. [Cache-aware](#) versions of the merge sort algorithm, whose operations have been specifically chosen to minimize the movement of pages in and out of a machine's memory cache, have been proposed. For example, the **tiled merge sort** algorithm stops partitioning subarrays when

Merge sort type algorithms allowed large data sets to be sorted on early computers that had small random access memories by modern standards. Records were stored on [magnetic tape](#) and processed on banks of magnetic tape drives, such as these [IBM 729s](#).

subarrays of size  $S$  are reached, where  $S$  is the number of data items fitting into a CPU's cache. Each of these subarrays is sorted with an in-place sorting algorithm such as [insertion sort](#), to discourage memory swaps, and normal merge sort is then completed in the standard recursive fashion. This algorithm has demonstrated better performance on machines that benefit from cache optimization. ([LaMarca & Ladner 1997](#))

[Kronrod \(1969\)](#) suggested an alternative version of merge sort that uses constant additional space. This algorithm was later refined. ([Katajainen, Pasanen & Teuhola 1996](#))

Also, many applications of [external sorting](#) use a form of merge sorting where the input get split up to a higher number of sublists, ideally to a number for which merging them still makes the currently processed set of [pages](#) fit into main memory.

## Parallel merge sort [\[edit\]](#)

Merge sort parallelizes well due to use of the divide-and-conquer method. Several parallel variants are discussed in the third edition of Cormen, Leiserson, Rivest, and Stein's *Introduction to Algorithms*.<sup>[9]</sup> The first of these can be very easily expressed in a pseudocode with [fork](#) and [join](#) keywords:

```
/* inclusive/exclusive indices */
procedure mergesort(A, lo, hi):
    if lo+1 < hi: /* if two or more elements */
        mid =  $\lfloor (lo + hi) / 2 \rfloor$ 
        fork mergesort(A, lo, mid)
        mergesort(A, mid, hi)
    join
    merge(A, lo, mid, hi)
```

This algorithm is a trivial modification from the serial version, but its speedup is not impressive: it runs in  $\Theta(n)$  time, which is somewhat faster than the serial version's  $\Theta(n \log n)$  time, but still has only  $\Theta(\log n)$  parallelism. A parallel [merge algorithm](#) to not only parallelize the recursive division of the array, but also the merge operation leads to a better parallel sort with parallelism  $\Theta(n / \log n)$ . Such a sort can perform well in practice when combined with a fast stable sequential sort, such as [insertion sort](#), and a fast sequential merge as a base case for merging small arrays.<sup>[10]</sup> Merge sort was one of the first sorting algorithms where optimal speed up was achieved, with Richard Cole using a clever subsampling algorithm to ensure  $O(1)$  merge.<sup>[11]</sup> Other sophisticated parallel sorting algorithms can achieve the same or better time bounds with a lower constant. For example, in 1991 David Powers described a parallelized [quicksort](#) (and a related [radix sort](#)) that can operate in  $O(\log n)$  time on a CRCW [PRAM](#) with  $n$  processors by performing partitioning implicitly.<sup>[12]</sup> Powers<sup>[13]</sup> further shows that a pipelined version of Batcher's [Bitonic Mergesort](#) at  $O(\log^2 n)$  time on a butterfly [sorting network](#) is in practice actually faster than his  $O(\log n)$  sorts on a [PRAM](#), and he provides detailed discussion of the hidden overheads in comparison, radix and parallel sorting.

## Comparison with other sort algorithms [\[edit\]](#)

Although [heapsort](#) has the same time bounds as merge sort, it requires only  $\Theta(1)$  auxiliary space instead of merge sort's  $\Theta(n)$ . On typical modern architectures, efficient [quicksort](#) implementations generally outperform mergesort for sorting RAM-based arrays.<sup>[citation needed]</sup> On the other hand, merge sort is a stable sort and is more efficient at handling slow-to-access sequential media. Merge sort is often the best choice for sorting a [linked list](#): in this situation it is relatively easy to implement a merge sort in such a way that it requires only  $\Theta(1)$  extra space, and the slow random-access performance of a linked list makes some other algorithms (such as quicksort) perform poorly, and others (such as heapsort) completely impossible.

As of [Perl 5.8](#), merge sort is its default sorting algorithm (it was quicksort in previous versions of Perl). In [Java](#), the [Arrays.sort\(\)](#) [↗](#) methods use merge sort or a tuned quicksort depending on the datatypes and for implementation efficiency switch to [insertion sort](#) when fewer than seven array elements are being sorted.<sup>[14]</sup> [Python](#) uses [Timsort](#), another tuned hybrid of merge sort and insertion sort, that has become the standard sort algorithm in [Java SE 7](#),<sup>[15]</sup> on the [Android platform](#),<sup>[16]</sup> and in [GNU Octave](#).<sup>[17]</sup>

The Wikibook *Algorithm implementation* has a page on the topic of: [Merge sort](#)

<span>v · t · e</span>	Sorting algorithms	<span>[hide]</span>
<b>Theory</b>	Computational complexity theory · Big O notation · Total order · Lists · Inplacement · Stability · Comparison sort · Adaptive sort · Sorting network · Integer sorting	
<b>Exchange sorts</b>	Bubble sort · Cocktail sort · Odd–even sort · Comb sort · Gnome sort · Quicksort · Stooge sort · Bogosort	
<b>Selection sorts</b>	Selection sort · Heapsort · Smoothsort · Cartesian tree sort · Tournament sort · Cycle sort	
<b>Insertion sorts</b>	Insertion sort · Shellsort · Splaysort · Tree sort · Library sort · Patience sorting	
<b>Merge sorts</b>	<b>Merge sort</b> · Cascade merge sort · Oscillating merge sort · Polyphase merge sort · Strand sort	
<b>Distribution sorts</b>	American flag sort · Bead sort · Bucket sort · Burtsort · Counting sort · Pigeonhole sort · Proxmap sort · Radix sort · Flashsort	
<b>Concurrent sorts</b>	Bitonic sorter · Batchmer odd–even mergesort · Pairwise sorting network	
<b>Hybrid sorts</b>	Block sort · Timsort · Introsort · Spreadsort · JSort	
<b>Other</b>	Topological sorting · Pancake sorting · Spaghetti sort
