***n*-body problem**

From Wikipedia, the free encyclopedia

This article is about the problem in classical mechanics. For the problem in quantum mechanics, see [Many-body problem](#). For engineering problems and simulations involving many components, see [Multibody system](#) and [Multibody simulation](#).

In [physics](#), the ***n*-body problem** is the problem of predicting the individual motions of a group of [celestial objects](#) interacting with each other [gravitationally](#).^[1] Solving this problem has been motivated by the desire to understand the motions of the [Sun](#), [Moon](#), [planets](#) and the visible [stars](#). In the 20th century, understanding the dynamics of [globular cluster](#) star systems became an important *n*-body problem.^[2] The *n*-body problem in [general relativity](#) is considerably more difficult to solve.

The classical physical problem can be informally stated as: *given the quasi-steady orbital properties (instantaneous position, velocity and time)*^[3] *of a group of celestial bodies, predict their interactive forces; and consequently, predict their true orbital motions for all future times.*^[4]

To this purpose the [two-body problem](#) has been completely solved and is discussed below, as is the famous *restricted 3-Body Problem*.^[5]

History [edit]

Knowing three orbital positions of a planet's orbit – positions obtained by Sir [Isaac Newton](#) (1643-1727) from astronomer [John Flamsteed](#)^[6] – Newton was able to produce an equation by straightforward analytical geometry, to predict a planet's motion; i.e., to give its orbital properties: position, orbital diameter, period and orbital velocity.^[7] Having done so he and others soon discovered over the course of a few years, those equations of motion did not predict some orbits very well or even correctly.^[8] Newton realized it was because gravitational interactive forces amongst all the planets was affecting all their orbits.

The above discovery goes right to the heart of the matter as to what exactly the *n*-body problem is physically: as Newton realized, it is not sufficient to just specify the initial position and velocity, or three orbital positions either, to determine a planet's true orbit: *the gravitational interactive forces have to be known too*. Thus came the awareness and rise of the n-body "problem" in the early 17th century. These gravitational attractive forces do conform to Newton's *Laws of Motion* and to his *Law of Universal Gravitation*, but the many multiple (*n*-body)

interactions have historically made any exact solution intractable. Ironically, this conformity led to the wrong approach.

After Newton's time the n -body problem historically was not stated correctly *because it did not include a reference to those gravitational interactive forces*. Newton does not say it directly but implies in his [Principia](#) the n -body problem is unsolvable because of those gravitational interactive forces.^[9] Newton said^[10] in his Principia, paragraph 21:

And hence it is that the attractive force is found in both bodies. The Sun attracts Jupiter and the other planets, Jupiter attracts its satellites and similarly the satellites act on one another. And although the actions of each of a pair of planets on the other can be distinguished from each other and can be considered as two actions by which each attracts the other, yet inasmuch as they are between the same, two bodies they are not two but a simple operation between two termini. Two bodies can be drawn to each other by the contraction of rope between them. The cause of the action is twofold, namely the disposition of each of the two bodies; the action is likewise twofold, insofar as it is upon two bodies; but insofar as it is between two bodies it is single and one ...

Newton concluded via his 3rd Law that "according to this Law all bodies must attract each other." This last statement, which implies the existence of gravitational interactive forces, is key.

As shown below, the problem also conforms to [Jean Le Rond D'Alembert's](#) non-Newtonian 1st and 2nd *Principles* and to the nonlinear n -body problem algorithm, the latter allowing for a closed form solution for calculating those interactive forces.

The problem of finding the general solution of the n -body problem was considered very important and challenging. Indeed in the late 19th century King [Oscar II of Sweden](#), advised by [Gösta Mittag-Leffler](#), established a prize for anyone who could find the solution to the problem. The announcement was quite specific:

Given a system of arbitrarily many mass points that attract each according to Newton's law, under the assumption that no two points ever collide, try to find a representation of the coordinates of each point as a series in a variable that is some known function of time and for all of whose values the series **converges uniformly**.

In case the problem could not be solved, any other important contribution to classical mechanics would then be considered to be prize-worthy. The prize was awarded to Poincaré, even though he did not solve the original problem. (The first version of his contribution even contained a serious error^[11]). The version finally printed contained many important ideas which led to the development of [chaos theory](#). The problem as stated originally was finally solved by [Karl Fritiof Sundman](#) for $n = 3$.

General formulation [\[edit\]](#)

The n -body problem considers N point masses $m_i, i = 1, 2, \dots, N$ in an [inertial reference frame](#) in three dimensional space \mathbb{R}^3 moving under the influence of mutual gravitational attraction. Each mass m_i has a position vector \mathbf{q}_i . [Newton's second law](#) says that mass times acceleration $m_i d^2 \mathbf{q}_i / dt^2$ is equal to the sum of the forces on the mass. [Newton's law of gravity](#) says that the gravitational force felt on mass m_i by a single mass m_j is given by^[12]

$$\mathbf{F}_{ij} = \frac{G m_i m_j (\mathbf{q}_j - \mathbf{q}_i)}{\|\mathbf{q}_j - \mathbf{q}_i\|^3},$$

where G is the [gravitational constant](#) and $\|\mathbf{q}_j - \mathbf{q}_i\|$ is the magnitude of the distance between \mathbf{q}_i and \mathbf{q}_j .

Summing over all masses yields the n -body [equations of motion](#):

$$m_i \frac{d^2 \mathbf{q}_i}{dt^2} = \sum_{j=1, j \neq i}^N \frac{G m_i m_j (\mathbf{q}_j - \mathbf{q}_i)}{\|\mathbf{q}_j - \mathbf{q}_i\|^3} = \frac{\partial U}{\partial \mathbf{q}_i}$$

where U is the *self-potential* energy

$$U = \sum_{1 \leq i < j \leq N} \frac{G m_i m_j}{\|\mathbf{q}_j - \mathbf{q}_i\|}.$$

Defining the momentum to be $\mathbf{p}_i = m_i d\mathbf{q}_i / dt$, [Hamilton's equations of motion](#) for the n -body problem become^[13]

$$\frac{d\mathbf{q}_i}{dt} = \frac{\partial H}{\partial \mathbf{p}_i} \quad \frac{d\mathbf{p}_i}{dt} = -\frac{\partial H}{\partial \mathbf{q}_i},$$

where the [Hamiltonian function](#) is

$$H = T + U$$

and T is the [kinetic energy](#)

$$T = \sum_{i=1}^N \frac{\|\mathbf{p}_i\|^2}{2m_i}.$$

Hamilton's equations show that the n -body problem is a system of $6N$ first-order [differential equations](#), with $6N$ [initial conditions](#) as $3N$ initial position coordinates and $3N$ initial momentum values.

Symmetries in the n -body problem yield global [integrals of motion](#) that simplify the problem.^[14] [Translational symmetry](#) of the problem results in the [center of mass](#)

$$\mathbf{C} = \frac{\sum_{i=1}^N m_i \mathbf{q}_i}{\sum_{i=1}^N m_i}$$

moving with constant velocity, so that $\mathbf{C} = \mathbf{L}_0 t + \mathbf{C}_0$, where \mathbf{L}_0 is the linear momentum and \mathbf{C}_0 is the initial position. The constants of motion L_0 and \mathbf{C}_0 represent six integrals of the motion. [Rotational symmetry](#) results in the total [angular momentum](#) being constant

$$\mathbf{A} = \sum_{i=1}^N \mathbf{q}_i \times \mathbf{p}_i,$$

where \times is the [cross product](#). The three components of the total angular momentum \mathbf{A} yield three more constants of the motion. The last general constant of the motion is given by the [conservation of energy](#) H . Hence, every n -body problem has ten integrals of motion.

Because T and U are [homogeneous functions](#) of degree 2 and -1 , respectively, the equations of motion have a [scaling invariance](#): if $\mathbf{q}_i(t)$ is a solution, then so is $\lambda^{-2/3} \mathbf{q}_i(\lambda t)$ for any $\lambda > 0$.^[15]

The [moment of inertia](#) of an n -body system is given by

$$I = \sum_{i=1}^N m_i \mathbf{q}_i \cdot \mathbf{q}_i = \sum_{i=1}^N m_i \|\mathbf{q}_i\|^2$$

and the *virial* is given by $Q = (1/2)dI/dt$. Then the *Lagrange-Jacobi formula* states that^[16]

$$\frac{d^2 I}{dt^2} = 2T - U.$$

For systems in *dynamic equilibrium*, the long-term time average of $\langle d^2 I / dt^2 \rangle$ is zero. Then on average the total kinetic energy is half the total potential energy, $\langle T \rangle = \langle U \rangle / 2$, which is an example of the [virial theorem](#) for gravitational systems.^[17] If M is the total mass and R a characteristic size of the system (for example, the radius containing half the mass of the system), then the critical time for a system to settle down to a dynamic equilibrium is $t_{\text{cr}} = \sqrt{GM/R^3}$.^[18]

Special cases [\[edit\]](#)

Two-body problem [\[edit\]](#)

Main article: [Two-body problem](#)

Any discussion of planetary interactive forces has always started historically with the [two-body problem](#). The purpose of this Section is to relate the real complexity in calculating any planetary forces. Note in this Section also, several subjects, such as [gravity](#), [barycenter](#), [Kepler's Laws](#), etc.; and in the following Section too ([Three-body problem](#)) are discussed on other Wikipedia pages. Here though, these subjects are discussed from the perspective of the n -body problem.

The two-body problem ($N = 2$) was completely solved by [Johann Bernoulli](#) (1667-1748) by *classical* theory (and not by Newton) by assuming the main point-mass was *fixed*, is outlined here.^[19] Consider then the motion of two bodies, say Sun-Earth, with the Sun *fixed*, then:

$$m_1 \mathbf{a}_1 = \frac{Gm_1 m_2}{r_{12}^3} (\mathbf{r}_2 - \mathbf{r}_1) \quad \text{Sun-Earth}$$

$$m_2 \mathbf{a}_2 = \frac{Gm_1 m_2}{r_{21}^3} (\mathbf{r}_1 - \mathbf{r}_2) \quad \text{Earth-Sun}$$

The equation describing the motion of mass m_2 relative to mass m_1 is readily obtained from the differences between these two equations and after canceling common terms gives: $\alpha + (\eta/r^3)\mathbf{r} = \mathbf{0}$, where

- $\mathbf{r} = \mathbf{r}_2 - \mathbf{r}_1$ is the vector position of m_2 relative to m_1 ;
- α is the *Eulerian* acceleration $d^2\mathbf{r}/dt^2$;
- and $\eta = G(m_1 + m_2)$.

The equation $\alpha + (\eta/r^3)\mathbf{r} = \mathbf{0}$ is the fundamental differential equation for the two-body problem Bernoulli solved in 1734. Notice for this approach forces have to be determined first, then the equation of motion resolved. This differential equation has elliptic, or parabolic or hyperbolic solutions^{[20], [21], [22]}

It is incorrect to think of m_1 (the Sun) as fixed in space when applying Newton's *Law of Universal Gravitation*, and to do so leads to erroneous results. The fixed point for two isolated gravitationally interacting bodies is their mutual **barycenter**, and this **two-body problem** can be solved exactly, such as using **Jacobi coordinates** relative to the barycenter.

Dr. Clarence Clemminshaw calculated the approximate position of the Solar System's barycenter, a result achieved mainly by combining only the masses of Jupiter and the Sun. *Science Program* stated in reference to his work:

"The Sun contains 98 per cent of the mass in the solar system, with the superior planets beyond Mars accounting for most of the rest. On the average, the center of the mass of the Sun-Jupiter system, when the two most massive objects are considered alone, lies 462,000 miles from the Sun's center, or some 30,000 miles above the solar surface! Other large planets also influence the center of mass of the solar system, however. In 1951, for example, the systems' center of mass was not far from the Sun's center because Jupiter was on the opposite side from Saturn, Uranus and Neptune. In the late 1950s, when all four of these planets were on the same side of the Sun, the system's center of mass was more than 330,000 miles from the solar surface, Dr. C. H. Clemminshaw of Griffith Observatory in Los Angeles has calculated."^[23]

The Sun wobbles as it rotates around the galactic center, dragging the Solar System and Earth along with it. What mathematician **Kepler** did in arriving at his three famous equations was curve-fit the apparent motions of the planets using **Tycho Brahe**'s data, and *not* curve-fitting their true circular motions about the Sun (see Figure). Both **Robert Hooke** and Newton were well aware that Newton's *Law of Universal Gravitation* did not hold for the forces associated with elliptical orbits.^[10] In fact, Newton's *Universal Law* does not account for the orbit of Mercury, the asteroid belt's gravitational behavior, or **Saturn's rings**.^[24] Newton stated (in the 11th Section of the Principia) that the main reason, however, for failing to predict the forces for elliptical orbits was that his math model was for a body confined to a situation that hardly existed in the real world, namely, the motions of bodies attracted toward an unmoving center. Some present physics and astronomy textbooks don't emphasize the negative significance of Newton's assumption and end up teaching that his math model is in effect reality. It is to be understood that the classical two-body problem solution above is a mathematical idealization. See also **Kepler's first law of planetary motion**.

Some modern writers have criticized Newton's *fixed* Sun as emblematic of a school of reductive thought - see Truesdell's *Essays in the History of Mechanics* referenced below. An aside: *Newtonian* physics doesn't include (among other things) **relative motion** and may be the root of the reason Newton "*fixed*" the Sun.^{[25][26]}

Three-body problem ^[edit]

Main article: [Three-body problem](#)

This section relates a historically important n -body problem solution after simplifying assumptions were made.

In the past not much was known about the n -body problem for n equal to or greater than three.^[27] The case for $n = 3$ has been the most studied. Many earlier attempts to understand the *Three-body problem* were quantitative, aiming at finding explicit solutions for special situations.

- In 1687 [Isaac Newton](#) published in the Principia the first steps in the study of the problem of the movements of three bodies subject to their mutual gravitational attractions, but his efforts resulted in verbal descriptions and geometrical sketches; see especially Book 1, Proposition 66 and its corollaries (Newton, 1687 and 1999 (transl.), see also Tisserand, 1894).
- In 1767 [Euler](#) found [collinear](#) motions, in which three bodies of any masses move proportionately along a fixed straight line. The [circular restricted three-body problem](#) is the special case in which two of the bodies are in circular orbits (approximated by the [Sun-Earth-Moon](#) system and many others).
- In 1772 [Lagrange](#) discovered two classes of periodic solution, each for three bodies of any masses. In one class, the bodies lie on a rotating straight line. In the other class, the bodies lie at the vertices of a rotating equilateral triangle. In either case, the paths of the bodies will be conic sections. Those solutions led to the study of *central configurations*, for which $\ddot{\mathbf{q}} = k\mathbf{q}$ for some constant $k > 0$.
- A major study of the Earth-Moon-Sun system was undertaken by [Charles-Eugène Delaunay](#), who published two volumes on the topic, each of 900 pages in length, in 1860 and 1867. Among many other accomplishments, the work already hints at chaos, and clearly demonstrates the problem of so-called "*small denominators*" in [perturbation theory](#).
- In 1917 [Forest Ray Moulton](#) published his now classic, *An Introduction to Celestial Mechanics* (see references) with its plot of the *Restricted Three-body Problem* solution (see figure below).^[28] An aside, see Meirovitch's book, pages 414 and 413 for his *Restricted Three-body Problem* solution.^[29]

Moulton's solution may be easier to visualize (and definitely easier to solve) if one considers the more massive body (e.g., [Sun](#)) to be "*stationary*" in space, and the less massive body (e.g., [Jupiter](#)) to orbit around it, with the equilibrium points ([Lagrangian points](#)) maintaining the 60-degree spacing ahead of, and behind, the less massive body almost in its orbit (although in reality neither of the bodies are truly stationary, as they both orbit the center of mass of the whole system—about the barycenter). For sufficiently small mass ratio of the primaries, these triangular equilibrium points are stable, such that (nearly) massless particles will orbit about these points as they orbit around the larger primary (Sun). The five equilibrium points of the circular problem are known as the Lagrangian points. See figure below:

In the *Restricted 3-Body Problem* math model figure above (ref. Moulton), the Lagrangian points L_4 and L_5 are where the [Trojan planetoids](#) resided (see [Lagrangian point](#)); m_1 is the Sun and m_2 is Jupiter. L_2 is where the asteroid belt is. It has to be realized for this model, this whole Sun-Jupiter diagram is rotating about its barycenter. The *Restricted 3-Body Problem* solution predicted the Trojan planetoids before they were first seen. The h -circles and closed loops echo the electromagnetic fluxes issued from the Sun and Jupiter. It is conjectured, contrary to Richard H. Batin's conjecture (see References), the two h_1 's are gravity sinks, in and where gravitational forces are zero, and the reason the Trojan planetoids are trapped there. The total amount of mass of the planetoids is unknown.

The *Restricted Three-body Problem* assumes the [mass](#) of one of the bodies is negligible.^[citation needed] For a discussion of the case where the negligible body is a satellite of the body of lesser mass, see [Hill sphere](#); for binary systems, see [Roche lobe](#). Specific solutions to the *Three-body problem* result in [chaotic](#) motion with no obvious sign of a repetitious path.^[citation needed]

The restricted problem (both circular and elliptical) was worked on extensively by many famous mathematicians and physicists, most notably by [Poincaré](#) at the end of the 19th century. Poincaré's work on the *Restricted Three-body Problem* was the foundation of [deterministic chaos theory](#).^[citation needed] In the restricted problem, there exist five [equilibrium points](#). Three are collinear with the masses (in the rotating frame) and are unstable. The remaining two are located on the third vertex of both equilateral triangles of which the two bodies are the first and second vertices.

Planetary problem ^[edit]

The *planetary problem* is the n -body problem in the case that one of the masses is much larger than all the others. A prototypical example of a planetary problem is the Sun-[Jupiter-Saturn](#) system, where the mass of the Sun is about 1000 times bigger than the masses of Jupiter or Saturn.^[15] An approximate solution to the problem is to decompose it into $N - 1$ pairs of star-planet [Kepler problems](#), treating interactions among the planets as

perturbations. [Perturbative approximation](#) works well as long as there are no [orbital resonances](#) in the system, that is none of the ratios of unperturbed Kepler frequencies is a rational number. Resonances appear as small denominators in the expansion.

The existence of resonances and small denominators led to the important question of stability in the planetary problem: do planets, in nearly circular orbits around a star, remain in stable or bounded orbits over time?^{[15][30]} In 1963, [Vladimir Arnold](#) proved using [KAM theory](#) a kind of stability of the planetary problem: there exists a set of positive measure of [quasiperiodic](#) orbits in the case of the planetary problem restricted to the plane.^[30] In the KAM theory, chaotic planetary orbits would be bounded by quasiperiodic KAM tori. Arnold's result was extended to a more general theorem by Féjóz and Herman in 2004.^[31]

Central configurations [\[edit\]](#)

A *central configuration* $\mathbf{q}_1(0), \dots, \mathbf{q}_N(0)$ is an initial configuration such that if the particles were all released with zero velocity, they would all collapse toward the center of mass \mathbf{C} .^[30] Such a motion is called *homothetic*. Central configurations may also give rise to *homographic motions* in which all masses moves along Keplerian trajectories (elliptical, circular, parabolic, or hyperbolic), with all trajectories having the same eccentricity e . For elliptical trajectories, $e = 1$ corresponds to homothetic motion and $e = 0$ gives a *relative equilibrium motion* in which the configuration remains an isometry of the initial configuration, as if the configuration was a rigid body.^[32] Central configurations have played an important role in understanding the [topology](#) of [invariant manifolds](#) created by fixing the first integrals of a system.

n-body choreography [\[edit\]](#)

Main article: [n-body choreography](#)

Solutions in which all masses move on the *same* curve without collisions are called choreographies.^[33] A choreography for $N = 3$ was discovered by Lagrange in 1772 in which three bodies are situated at the vertices of an [equilateral triangle](#) in the rotating frame. A [figure eight](#) choreography for $N = 3$ was found numerically by C. Moore in 1993 and generalized and proven by A. Chenciner and R. Montgomery in 2000. Since then, many other choreographies have been found for $N \geq 3$.

Analytic approaches [\[edit\]](#)

For every solution of the problem, not only applying an [isometry](#) or a time shift but also a [reversal of time](#) (unlike in the case of friction) gives a solution as well.^[*citation needed*]

In the physical literature about the n -body problem ($n \geq 3$), sometimes reference is made to *the impossibility of solving the n -body problem* (via employing the above approach).^[*citation needed*] However, care must be taken when discussing the 'impossibility' of a solution, as this refers only to the method of first integrals (compare the theorems by [Abel](#) and [Galois](#) about the impossibility of solving [algebraic equations of degree five](#) or higher by means of formulas only involving roots).

Power series solution [\[edit\]](#)

One way of solving the classical *n*-body problem is "the *n*-body problem by [Taylor series](#)", which is an implementation of the [Power series solution of differential equations](#).

We start by defining the system of [differential equations](#):^[*citation needed*]

$$\frac{d^2 \mathbf{x}_i(t)}{dt^2} = G \sum_{k=1, k \neq i}^n \frac{m_k (\mathbf{x}_k(t) - \mathbf{x}_i(t))}{|\mathbf{x}_k(t) - \mathbf{x}_i(t)|^3},$$

As $\mathbf{x}_i(t = t_0)$ and $d\mathbf{x}_i(t)/dt|_{t=t_0}$ are given as initial conditions, every $d^2\mathbf{x}_i(t)/dt^2$ are known. Differentiating $d^2\mathbf{x}_i(t)/dt^2$ results in $d^3\mathbf{x}_i(t)/dt^3$ which at t_0 which is also known, and the Taylor series is constructed iteratively.^[*clarification needed*]

A generalized Sundman global solution [\[edit\]](#)

In order to generalize Sundman's result for the case $n > 3$ (or $n = 3$ and $c = 0$)^[*clarification needed*] one has to face two obstacles:

1. As it has been shown by Siegel, collisions which involve more than two bodies cannot be regularized analytically, hence Sundman's regularization cannot be generalized.
2. The structure of singularities is more complicated in this case: other types of singularities may occur (see [below](#)).

Lastly, Sundman's result was generalized to the case of $n > 3$ bodies by [Q. Wang](#) in the 1990s. Since the

structure of singularities is more complicated, Wang had to leave out completely the questions of singularities. The central point of his approach is to transform, in an appropriate manner, the equations to a new system, such that the interval of existence for the solutions of this new system is $[0, \infty)$.

Singularities of the n -body problem [\[edit\]](#)

There can be two types of singularities of the n -body problem:

- collisions of two or more bodies, but for which $\mathbf{q}(t)$ (the bodies' positions) remains finite. (In this mathematical sense, a "collision" means that two point-like bodies have identical positions in space.)
- singularities in which a collision does not occur, but $\mathbf{q}(t)$ does not remain finite. In this scenario, bodies diverge to infinity in a finite time, while at the same time tending towards zero separation (an imaginary collision occurs "at infinity").

The latter ones are called Painlevé's conjecture (no-collisions singularities). Their existence has been conjectured for $n > 3$ by [Painlevé](#) (see [Painlevé conjecture](#)). Examples of this behavior for $n=5$ have been constructed by Xia^[34] and a heuristic model for $n=4$ by Gerver.^[35] [Donald G. Saari](#) has shown that for 4 or fewer bodies, the set of initial data giving rise to singularities has [measure](#) zero.^[36]

Simulation [\[edit\]](#)

Main article: [N-body simulation](#)

While there are analytic solutions available for the classical (ie. non-relativistic) two-body problem and for selected configurations with $N > 2$, in general n -body problems must be solved or simulated using numerical methods.^[18]

Few bodies [\[edit\]](#)

For a small number of bodies, an n -body problem can be solved using **direct methods**, also called **particle-particle methods**. These methods numerically integrate the differential equations of motion. Numerical integration for this problem can be a challenge for several reasons. First, the gravitational potential is singular; it goes to infinity as the distance between two particles goes to zero. The gravitational potential may be *softened* to remove the singularity at small distances.^[18]

$$U_{\epsilon} = \sum_{1 \leq i < j \leq N} \frac{Gm_i m_j}{(\|\mathbf{q}_j - \mathbf{q}_i\|^2 + \epsilon)^{1/2}}.$$

Second, in general for $N > 2$, the N -body problem is [chaotic](#),^[37] which means that even small errors in integration may grow exponentially in time. Third, a simulation may be over large stretches of model time (e.g., millions of years) and numerical errors accumulate as integration time increases.

There are a number of techniques to reduce errors in numerical integration.^[18] Local coordinate systems are used to deal with widely differing scales in some problems, for example an Earth-Moon coordinate system in the context of a solar system simulation. Variational methods and perturbation theory can yield approximate analytic trajectories upon which the numerical integration can be a correction. The use of a [symplectic integrator](#) ensures that the simulation obeys Hamilton's equations to a high degree of accuracy and in particular that energy is conserved.

Many bodies [\[edit\]](#)

Direct methods using numerical integration require on the order of $N^2/2$ computations to evaluate the potential energy over all pairs of particles, and thus have a [time complexity](#) of $O(N^2)$. For simulations with many particles, the $O(N^2)$ factor makes large-scale calculations especially time consuming.^[18]

A number of approximate methods have been developed that reduce the time complexity relative to direct methods.^[18]

- **Tree code methods**, such as a [Barnes-Hut simulation](#), are *collisionless* methods used when close encounters among pairs are not important and distant particle contributions do not need to be computed to high accuracy. The potential of a distant group of particles is computed using a [multipole expansion](#) of the potential. This approximation allows for a reduction in complexity to $O(N \log(N))$.
- **Fast multipole methods** take advantage of the fact that the multipole-expanded forces from distant particles are similar for particles close to each other. It is claimed that this further approximation reduces the complexity to $O(N)$.^[18]
- **Particle mesh methods** divide up simulation space into a three dimensional grid onto which the mass

density of the particles is interpolated. Then calculating the potential becomes a matter of solving a [Poisson equation](#) on the grid, which can be computed in $O(N \log(N))$ time using [fast Fourier transform](#) techniques. Using [adaptive mesh refinement](#) or [multigrid](#) techniques can further reduce the complexity of the methods.

- **P3M** and **PM-Tree methods** are hybrid methods that use the particle mesh approximation for distant particles, but use more accurate methods for close particles (within a few grid intervals). P3M stands for P^3M or *Particle-Particle-Particle-Mesh* and uses direct methods with softened potentials at close range. PM-Tree methods instead use tree codes at close range. As with particle mesh methods, adaptive meshes can increase computational efficiency.
- **Mean field methods** approximate the system of particles with a time-dependent [Boltzmann equation](#) representing the mass density that is coupled to a self-consistent Poisson equation representing the potential. It is a type of [smoothed-particle hydrodynamics](#) approximation suitable for large systems.

Strong gravitation [\[edit\]](#)

In astrophysical systems with strong gravitational fields, such as those near the [event horizon](#) of a [black hole](#), n -body simulations must take into account [general relativity](#); such simulations are the domain of [numerical relativity](#). Numerically simulating the [Einstein field equations](#) is extremely challenging^[18] and a [parameterized post-Newtonian formalism](#) (PPN), such as the [Einstein–Infeld–Hoffmann equations](#), is used if possible. The [two-body problem in general relativity](#) is analytically solvable only for the Kepler problem, in which one mass is assumed to be much larger than the other.^[38]

Other n -body problems [\[edit\]](#)

Most work done on the n -body problem has been on the gravitational problem. But there exist other systems for which n -body mathematics and simulation techniques have proven useful.

In large scale [electrostatics](#) problems, such as the simulation of [proteins](#) and cellular assemblies in [structural biology](#), the [Coulomb potential](#) has the same form as the gravitational potential, except that charges may be positive or negative, leading to repulsive as well as attractive forces.^[39] *Fast Coulomb solvers* are the electrostatic counterpart to fast multipole method simulators. These are often used with [periodic boundary conditions](#) on the region simulated and [Ewald summation](#) techniques are used to speed up computations.^[40]

In [statistics](#) and [machine learning](#), some models have [loss functions](#) of a form similar to that of the gravitational potential: a sum of kernel functions over all pairs of objects, where the kernel function depends on the distance between the objects in parameter space.^[41] Example problems that fit into this form include [all-nearest-neighbors](#) in [manifold learning](#), [kernel density estimation](#), and [kernel machines](#). Alternative optimizations to reduce the $O(N^2)$ time complexity to $O(N)$ have been developed, such as *dual tree* algorithms, that have applicability to the gravitational n -body problem as well.

Notes [\[edit\]](#)

- [^] Leimanis and Minorsky: Our interest is with Leimanis, who first discusses some history about the n -body problem, especially Ms. Kovalevskaya's ~1868-1888, twenty-year complex-variables approach, failure; **Section 1: The Dynamics of Rigid Bodies and Mathematical Exterior Ballistics** (Chapter 1, *the motion of a rigid body about a fixed point* (**Euler** and **Poisson** equations); Chapter 2, *Mathematical Exterior Ballistics*), good precursor background to the n -body problem; **Section 2: Celestial Mechanics** (Chapter 1, *The Uniformization of the Three-body Problem* (Restricted Three-body Problem); Chapter 2, *Capture in the Three-Body Problem*; Chapter 3, *Generalized n -body Problem*).
- [^] See references cited for Heggie and Hut.
- [^] *Quasi-steady* loads refers to the instantaneous inertial loads generated by instantaneous angular velocities and accelerations, as well as translational accelerations (9 variables). It is as though one took a photograph, which also recorded the instantaneous position and properties of motion. In contrast, a *steady-state* condition refers to a

- system's state being invariant to time; otherwise, the first derivatives and all higher derivatives are zero.
4. [^] R. M. Rosenberg states the *n*-body problem similarly (see References): *Each particle in a system of a finite number of particles is subjected to a Newtonian gravitational attraction from all the other particles, and to no other forces. If the initial state of the system is given, how will the particles move?* Rosenberg failed to realize, like everyone else, that it is necessary to determine the forces *first* before the motions can be determined.
 5. [^] A general, classical solution in terms of first integrals is known to be impossible. An exact theoretical solution for arbitrary *n* can be approximated via [Taylor series](#), but in practice such an [infinite series](#) must be truncated, giving at best only an approximate solution; and an approach now obsolete. In addition, the *n*-body problem may be solved using [numerical integration](#), but these, too, are approximate solutions; and again obsolete. See Sverre J. Aarseth's book **Gravitational N-body Simulations** listed in the References.
 6. [^] See David H. and Stephen P. H. Clark's **The Suppressed Scientific Discoveries of Stephen Gray and John Flamsteed, Newton's Tyranny**, W. H. Freeman and Co., 2001. A popularization of the historical events and bickering between those parties, but more importantly about the results they produced.
 7. [^] See "**Discovery of gravitation, A.D. 1666**" by [Sir David Brewster](#), in **The Great Events by Famous Historians**, Rossiter Johnson, LL.D. Editor-in-Chief, Volume XII, pp. 51-65, *The National Alumni*, 1905.
 8. [^] Rudolf Kurth has an extensive discussion in his book (see References) on planetary perturbations. An aside: these mathematically undefined planetary perturbations (wobbles) still exist undefined even today and planetary orbits have to be constantly updated, usually yearly. See *Astronomical Ephemeris and the American Ephemeris and Nautical Almanac*, prepared jointly by the Nautical Almanac Offices of the United Kingdom and the United States of America.
 9. [^] See **Principia**, Book Three, *System of the World*, "*General Scholium*," page 372, last paragraph. Newton was well aware his math model did not reflect physical reality. This edition referenced is from the **Great Books of the Western World**, Volume 34, which was translated by Andrew Motte and revised by [Florian Cajori](#). This same paragraph is on page 1160 in [Stephen Hawking's](#) huge **On the Shoulders of Giants**, 2002 edition; is a copy from Daniel Adee's 1848 addition. Cohen also has translated new editions: **Introduction to Newton's 'Principia'**, 1970; and **Isaac Newton's Principia, with Varian Readings**, 1972. Cajori also wrote a **History of Science**, which is on the Internet.

 19. [^] See Bate, Mueller, and White: Chapter 1, "**Two-Body Orbital Mechanics**," pp 1-49. These authors were from the *Dept. of Astronautics and Computer Science*, United States Air Force Academy. See Chapter 1. Their textbook is not filled with advanced mathematics.
 20. [^] For the classical approach, if the common [center of mass](#) (i.e., the barycenter) of the two bodies is considered *to be at rest*, then each body travels along a [conic section](#) which has a [focus](#) at the barycenter of the system. In the case of a hyperbola it has the branch at the side of that focus. The two conics will be in the same plane. The type of conic ([circle](#), [ellipse](#), [parabola](#) or [hyperbola](#)) is determined by finding the sum of the combined kinetic energy of two bodies and the [potential energy](#) when the bodies are far apart. (This potential energy is always a negative value; energy of rotation of the bodies about their axes is not counted here)
 - If the sum of the energies is negative, then they both trace out ellipses.
 - If the sum of both energies is zero, then they both trace out parabolas. As the distance between the bodies tends to infinity, their relative speed tends to zero.
 - If the sum of both energies is positive, then they both trace out hyperbolas. As the distance between the bodies tends to infinity, their relative speed tends to some positive number.
 21. [^] For this approach see Lindsay's **Physical Mechanics**, Chapter 3, "**Curvilinear Motion in a Plane**," and specifically paragraph 3-9, "**Planetary Motion**"; and continue reading on to the Chapter's end, pp. 83-96. Lindsay presentation goes a long way in explaining these latter comments for the fixed *2-body problem*; i.e., when the Sun is assumed fixed.
 22. [^] Note: The fact a parabolic orbit has zero energy arises from the assumption the gravitational potential energy goes to zero as the bodies get infinitely far apart. One could assign *any* value to the potential energy in the state of infinite separation. That state is assumed to have zero potential energy *by convention*.
 23. [^] Science Program's **The Nature of the Universe** states Clarence Clemminshaw (1902-1985) served as Assistant Director of *Griffith Observatory* from 1938-1958 and as Director from 1958-1969. Some publications by Clemminshaw, C. H.: **Celestial Speeds**, 4 1953, equation, Kepler, orbit, comet, Saturn, Mars, velocity; Clemminshaw, C. H.: **The Coming Conjunction of Jupiter and Saturn**, 7 1960, Saturn, Jupiter, observe, conjunction; Clemminshaw, C. H.: **The Scale of The Solar System**, 7 1959, Solar system, scale, Jupiter, sun, size, light.
