# Closest pair of points problem

From Wikipedia, the free encyclopedia  
(Redirected from [Closest pair problem](#))

The **closest pair of points problem** or **closest pair problem** is a problem of [computational geometry](#): given  $n$  points in [metric space](#), find a pair of points with the smallest distance between them. The closest pair problem for points in the Euclidean plane<sup>[1]</sup> was among the first geometric problems which were treated at the origins of the systematic study of the [computational complexity](#) of geometric algorithms.

A naive algorithm of finding distances between all pairs of points and selecting the minimum requires  $O(dn^2)$  time. It turns out that the problem may be solved in  $O(n \log n)$  time in a [Euclidean space](#) or  $L^p$  space of fixed dimension  $d$ . In the [algebraic decision tree model of computation](#), the  $O(n \log n)$  algorithm is optimal. The optimality follows from the observation that the [element uniqueness problem](#) (with the lower bound of  $\Omega(n \log n)$  for time complexity) is reducible to the closest pair problem: checking whether the minimal distance is 0 after the solving of the closest pair problem answers the question whether there are two coinciding points.

In the computational model which assumes that the [floor function](#) is computable in constant time the problem can be solved in  $O(n \log \log n)$  time.<sup>[2]</sup> If we allow randomization to be used together with the floor function, the problem can be solved in  $O(n)$  time.<sup>[3][4]</sup>

## Brute-force algorithm [\[edit\]](#)

The closest pair of points can be computed in  $O(n^2)$  time by performing a [brute-force search](#). To do that, one could compute the distances between all the  $n(n - 1) / 2$  pairs of points, then pick the pair with the smallest distance, as illustrated below.

```
minDist = infinity
for i = 1 to length(P) - 1
  for j = i + 1 to length(P)
    let p = P[i], q = P[j]
    if dist(p, q) < minDist:
      minDist = dist(p, q)
      closestPair = (p, q)
return closestPair
```

## Planar case [\[edit\]](#)

The problem can be solved in  $O(n \log n)$  time using the [recursive divide and conquer](#) approach, e.g., as follows:<sup>[1]</sup>

- Sort points according to their x-coordinates.
- Split the set of points into two equal-sized subsets by a vertical line  $x=x_{\text{mid}}$ .
- Solve the problem recursively in the left and right subsets. This yields the left-side and right-side minimum distances  $d_{\text{Lmin}}$  and  $d_{\text{Rmin}}$ , respectively.
- Find the minimal distance  $d_{\text{LRmin}}$  among the set of pairs of points in which one point lies on the left of the

dividing vertical and the second point lies to the right.

5. The final answer is the minimum among  $d_{Lmin}$ ,  $d_{Rmin}$ , and  $d_{LRmin}$ .

It turns out that step 4 may be accomplished in linear time. Again, a naive approach would require the calculation of distances for all left-right pairs, i.e., in quadratic time. The key observation is based on the following sparsity property of the point set. We already know that the closest pair of points is no further apart than  $dist = \min(d_{Lmin}, d_{Rmin})$ . Therefore for each point  $p$  to the left of the dividing line we have to compare the distances to the points that lie in the rectangle of dimensions  $(dist, 2 \cdot dist)$  to the right of the dividing line, as shown in the figure. And what is more, this rectangle can contain at most six points with pairwise distances at least  $d_{Rmin}$ . Therefore it is sufficient to compute at most  $6n$  left-right distances in step 4.<sup>[5]</sup> The recurrence relation for the number of steps can be written as  $T(n) = 2T(n/2) + O(n)$ , which we can solve using the [master theorem](#) to get  $O(n \log n)$ .

As the closest pair of points define an edge in the [Delaunay triangulation](#), and correspond to two adjacent cells in the [Voronoi diagram](#), the closest pair of points can be determined in linear time when we are given one of these two structures. Computing either the Delaunay triangulation or the Voronoi diagram takes  $O(n \log n)$  time. These approaches are not efficient for dimension  $d > 2$ , while the divide-and-conquer algorithm can be generalized to take  $O(n \log n)$  time for any constant value of  $d$ .

## Dynamic closest-pair problem [\[edit\]](#)

The [dynamic version](#) for the closest-pair problem is stated as follows:

- Given a [dynamic set](#) of objects, find algorithms and [data structures](#) for efficient recalculation of the closest pair of objects each time the objects are inserted or deleted.

If the [bounding box](#) for all points is known in advance and the constant-time floor function is available, then the expected  $O(n)$  space data structure was suggested that supports expected-time  $O(\log n)$  insertions and deletions and constant query time. When modified for the algebraic decision tree model, insertions and deletions would require  $O(\log^2 n)$  expected time.<sup>[6]</sup> It is worth noting, though, that the complexity of the dynamic closest pair algorithm cited above is exponential in the dimension  $d$ , and therefore such an algorithm becomes less suitable for high-dimensional problems.
