# Jump point search

From Wikipedia, the free encyclopedia

In [computer science](#), **jump point search** is an optimization to the [A\\* search algorithm](#) [pathfinding](#) algorithm for uniform-cost grids. It reduces symmetries in the search procedure by means of graph pruning,<sup>[1]</sup> eliminating certain nodes in the grid based on assumptions that can be made about the current node's neighbors, as long as certain conditions relating to the grid are satisfied. As a result, the algorithm can consider long "jumps" along straight (horizontal, vertical and diagonal) lines in the grid, rather than the small steps from one grid position to the next that ordinary A\* considers.<sup>[2]</sup>

Jump point search preserves A\*'s optimality, while potentially reducing its running time by an order of magnitude.<sup>[1]</sup>

## History [\[edit\]](#)

Harabor and Grastien's original publication provides algorithms for neighbour pruning and identifying successors.<sup>[1]</sup> The original algorithm for neighbour pruning allowed corner-cutting to occur, which meant the algorithm could only be used for moving agents with zero width; limiting its application to either real-life agents (e.g. robotics) or simulations (e.g. many games).

The authors presented modified pruning rules for applications where corner-cutting is not allowed the following year.<sup>[3]</sup> This paper also presents an algorithm for pre-processing a grid in order to minimise online search times.

A number of further optimisations were published by the authors in 2014.<sup>[4]</sup>

All the published modifications and optimisations preserve A\* optimality.
