Preface

Welcome to EMNLP-CoNLL 2007, an unprecedented joint meeting of the Conference on Empirical Methods in Natural Language Processing (EMNLP) and the Conference on Computational Natural Language Learning (CoNLL).

The conference is a joint effort of SIGDAT and SIGNLL, the ACL Special Interest Groups that usually organize the annual EMNLP and CoNLL conferences, respectively.

Our field is growing rapidly. This year, EMNLP-CoNLL considered a remarkable 398 submissions,[1] accepting 109 of them (for an acceptance rate of 27%). It is startling to realize that even the ACL conferences were not this large until two years ago.

Only 66 of the accepted papers were scheduled for presentation as talks, and 43 more as posters. We took pains to ensure that the poster sessions would be leisurely and interactive.

In addition, two sessions of the conference and 22 specially designated short papers in this volume are devoted to the CoNLL Shared Task competition, an annual tradition. The 2007 competition concerns dependency parsing, with both a multilingual track and a domain adaptation track.

Several innovations this year have received positive feedback and are worth mentioning:

- To encourage thorough citation of related work, a paper's References section was *not* counted against the 8-page limit for submitted papers or the 9-page limit for camera-ready papers.

  (Note that authors were allowed an extra page in the camera-ready version to help them effectively address reviewers' comments, following an innovation at EMNLP 2006.)

- The review form was redesigned (starting from the fine review form of EACL 2006) to provide clearer and more consistent guidance to reviewers, area chairs, and authors. Authors were directed to consult the review form, which was posted at the conference website, while preparing their submissions and when interpreting their review scores.

- Some of our submissions (fewer than 1/3) appeared to be revisions of rejected ACL 2007 submissions. Where possible, we tried to conserve valuable information and effort from the ACL 2007 reviewing process by re-assigning one, though only one, of the ACL reviewers to such a paper.

  Such re-reviewers were instructed to give the new, revised submission the fresh reading that it deserved, but they were also encouraged to bring up points that still applied from any of the ACL 2007 reviews or discussion.

[1] Of the original 419 submissions, 17 were withdrawn (usually upon acceptance elsewhere), and 4 more were rejected without review (for violating the conference's standards on length, anonymization, or plagiarism).

- By accepting many posters and presenting them all *simultaneously*, we hoped to accommodate a large audience without overcrowding at each poster.

  The large number of posters in turn required a long period for poster viewing. With a total of 5 hours spanning two receptions, a conferencegoer can engage with nearly half of the posters for 15 minutes of personalized discussion each. This makes the posters roughly as visible as the talks, which are split into parallel sessions.

- In addition to the Best Paper Award (see Session 1), we are considering organizing—if logistically feasible—an "Audience Choice" award for the most worthwhile *presentation* at the conference. Such a prize would reward authors who not only produced outstanding research but also communicated it clearly and enjoyably at the conference meeting.

It is my privilege to thank the many individuals—most of them listed on the following pages—whose generous efforts have made this conference possible. Foremost are the 16 dedicated area chairs and 370 reviewers, who worked together hard and thoughtfully to select this excellent program and provide valuable feedback to the authors. Also as part of the technical program, Joakim Nivre chaired the organization of the CoNLL Shared Task and the resulting short papers; Taku Kudo ably identified ACL 2007 resubmissions (see above); and Hal Daumé III kindly chaired the best paper award committee. Eric Ringger put a great deal of effort into producing this fine proceedings volume, with support from Su Jian, the ACL publications chair. Jan Hajic coordinated the many local arrangements, along with Priscilla Rasmussen, Anna Kotesovcova, Jiri Mirovsky, Pavel Stranak, Zdenek Zabokrtsky, and no doubt others; we are very grateful to them for making everything run smoothly in Prague. Antal van den Bosch, Dan Jurafsky, Eric Gaussier, and Ken Church provided much valuable advice over the past months based on their experience. Finally, let us not forget the hundreds of authors who actually produced the excellent research in this volume, and the invited speakers who graciously traveled a long way to enlighten us.

Enjoy the conference!

Jason Eisner
EMNLP-CoNLL Chair
May 2007

Organizers

Program Chair:

Jason Eisner, Johns Hopkins University

Area Chairs:

David Chiang, USC Information Sciences Institute
Alexander Clark, Royal Holloway University of London
Michael Collins, Massachusetts Institute of Technology
Hal Daumé III, University of Utah
Sanjeev Khudanpur, Johns Hopkins University
Katrin Kirchhoff, University of Washington
Dekang Lin, Google Inc.
Manabu Okumura, Tokyo Institute of Technology
Anoop Sarkar, Simon Fraser University
Suzanne Stevenson, University of Toronto
Tomek Strzalkowski, SUNY Albany
Carlo Strapparava, Istituto Trentino di Cultura
Hans Uszkoreit, Saarland University DFKI
Menno van Zaanen, Macquarie University
Marilyn Walker, University of Sheffield
Janyce Wiebe, University of Pittsburgh

CoNLL Shared Task Organizers:

Joakim Nivre, Växjö University and Uppsala University (chair)
Johan Hall, Växjö University
Sandra Kübler, Indiana University
Ryan McDonald, Google Inc.
Jens Nilsson, Växjö University
Sebastian Riedel, University of Edinburgh
Deniz Yuret, Koç University

Local Arrangements Chair:

Jan Hajic, Charles University

Publications Chair:

Eric Ringger, Brigham Young University

Reviewers:

John Aberdeen, Pieter Adriaans, Eugene Agichtein, Eneko Agirre, Gregory Aist, Enrique Alfonseca, Rie Ando, Necip Fazil Ayan, Leif Azzopardi;

Srinivas Bangalore, Marco Baroni, Regina Barzilay, Roberto Basili, Sugato Basu, Ron Bekkerman, Anja Belz, Sabine Bergler, Shane Bergsma, Dan Bikel, Misha Bilenko, Dave Blei, John Blitzer, Rens Bod, Bernd Bohnet, Johan Bos, Thorsten Brants, Eric Breck, Chris Brew, David Brooks, Charles Brown, Wray Buntine, John Burger;

Janet Cahn, Giuseppe Carenini, Xavier Carreras Pérez, Neus Català, Damir Ćavar, Joyce Chai, Yee Seng Chan, Jason Chang, Ciprian Chelba, Hsin-Hsi Chen, Stanley Chen, Colin Cherry, Yejin Choi, Jennifer Chu-Carroll, Grace Chung, Ken Church, Massimiliano Ciaramita, Alexander Clark, Stephen Clark, John Coleman, Paul Cook, Christophe Costa Florêncio, Mathias Creutz, Dan Cristea, András Csomai, Elsa Cubel, Silviu Cucerzan, Aron Culotta, James Curran;

Walter Daelemans, Robert Dale, R. I. Damper, Hal Daumé III, Eric Villemonte de la Clergerie, Maarten de Rijke, Christy Doran, Mark Dras, Amit Dubey, Kevin Duh;

Phil Edmonds, Noémie Elhadad, T. Mark Ellison, Ahmad Emami, Katrin Erk, David Evans, Rémi Eyraud;

Afsaneh Fazly, Marcello Federico, Karim Filali, Jenny Finkel, Kate Forbes-Riley, Eric Fosler-Lussier, George Foster, Mary Ellen Foster, Alexander Fraser, Dayne Freitag, Atsushi Fujii, Sean Fulop, Pascale Fung;

Tamas Gaal, Evgeniy Gabrilovich, Michel Galley, Michael Gamon, Claire Gardent, Jeroen Geertzen, Dale Gerdemann, Ulrich Germann, Daniel Gildea, Roxana Girju, John Goldsmith, Jade Goldstein, Sharon Goldwater, Cyril Goutte, Mark Greenwood, Gregory Grefenstette, Tom Griffiths, Iryna Gurevych;

Kadri Hacioglu, Aria Haghighi, Udo Hahn, Jan Hajic, Dilek Hakkani-Tür, Keith Hall, Susan Haller, Hilda Hardy, Mary Harper, Mary Hearne, Marti Hearst, Peter Heeman, James Henderson, John Henderson, Mark Hepple, Ryuichiro Higashinaka, Tsutomu Hirao, Graeme Hirst, Julia Hockenmaier, Chu-Ren Huang, Liang Huang, Annette Hulth, Rebecca Hwa;

Diana Inkpen, Kentaro Inui, Abe Ittycheriah;

Martin Jansche, Valentin Jijkoun, Mark Johnson, Kristiina Jokinen;

Min-Yen Kan, Hiroshi Kanayama, Damianos Karakos, Lauri Karttunen, Rohit Kate, Frank Keller, André Kempe, Adam Kilgarriff, Soo-Min Kim, George Kiraz, Katrin Kirchhoff, Chunyu Kit, Kevin Knight, Alistair Knott, Philipp Koehn, Rob Koeling, Alexander Koller, Grzegorz Kondrak, Stasinos Konstantopoulos, Terry Koo, Moshe Koppel, Anna Korhonen, András Kornai, Kimmo Koskenniemi, Sandra Kübler, Roland Kuhn, Shankar Kumar, Hong-Kwang Kuo, Sadao Kurohashi;

Philippe Langlais, Guy Lapalme, Mirella Lapata, Eric Laporte, Staffan Larsson, Geunbae Lee, Lillian Lee, Oliver Lemon, Lori Levin, Roger Levy, Hang Li, Wei Li, Chin-Yew Lin, Ying Lin, Bing Liu, Yang Liu, Adam Lopez, Saturnino Luz, Caroline Lyon;

Bernardo Magnini, Milind Mahajan, Fran cois Mairesse, Suresh Manandhar, Lidia Mangu, Gideon Mann, Christopher Manning, Daniel Marcu, Mitchell Marcus, Katja Markert, David Martinez, Yuji Matsumoto, Takuya Matsuzaki, Irina Matveeva, John Maxwell, David McClosky, Ryan McDonald, Susan McRoy, Helen Meng, Wolfgang Menzel, Detmar Meurers, Rada Mihalcea, Eleni Miltsakaki, Gilad Mishne, Yusuke Miyao, Marie-Francine Moens, Saif Mohammad, Mehryar Mohri, Christof Monz, Robert Moore, Tatsunori Mori, Alessandro Moschitti, Karin Müller, Dragos Stefan Munteanu;

Vivi Nastase, Roberto Navigli, Mark-Jan Nederhof, Ani Nenkova, Hwee Tou Ng, Grace Ngai, Patrick Nguyen, Vincent Ng, Malvina Nissim, Cheng Niu, Joakim Nivre, Tadashi Nomoto, David Novick;

Tim Oates, Franz Och, Kemal Oflazer, Paul Ogilvie, Miles Osborne;

Sebastian Padó, Tim Paek, Chris Pal, David Palmer, Martha Palmer, Bo Pang, Patrick Pantel, Marius Pasca, Rebecca Passonneau, Slav Petrov, Fabio Pianesi, Paul Piwek, Ferran Pla, Massimo Poesio, Richard Power, David Powers, Sameer Pradhan, Rashmi Prasad, Adam Przepiórkowski, Stephen Pulman, Vasin Punyakanok, Matthew Purver;

Yan Qu, Chris Quirk;

Owen Rambow, Deepak Ravichandran, Giuseppe Riccardi, Sebastian Riedel, Stefan Riezler, German Rigau, Ellen Riloff, Sophie Rosset;

Kenji Sagae, Magnus Sahlgren, Helmut Schmid, Patrick Schone, Sabine Schulte im Walde, Tanja Schultz, Dale Schuurmans, Holger Schwenk, Frédérique Segond, Satoshi Sekine, Izhak Shafran, Libin Shen, Khalil Sima'an, Michel Simard, Wojciech Skut, David A. Smith, Noah A. Smith, Rion Snow, Stephen Soderland, Swapna Somasundaran, Radu Soricut, Caroline Sporleder, Richard Sproat, Padmini Srinivasan, Brad Starkie, Manfred Stede, Mark Steedman, Mark Stevenson, Matthew Stone, Veselin Stoyanov, Carlo Strapparava, Michael Strube, Jian Su, Maosong Sun, Mihai Surdeanu, Charles Sutton, Hisami Suzuki, Jun Suzuki, Marc Swerts, Stan Szpakowicz;

Maite Taboada, Hiroya Takamura, Isabelle Tellier, Joel Tetreault, Simone Teufel, Mariët Theune, Franck Thollard, Christoph Tillmann, Kristina Toutanova, Vivian Tsang, Jun'ichi Tsujii, Dan Tufis;

Nicola Ueffing, Ozlem Uzuner;

Antal van den Bosch, Ashish Venugopal, Renata Vieira, Marc Vilain, Begoña Villada Moirón, Aline Villavicencio, Carl Vogel, Stephan Vogel, Piek Vossen;

Qin Wang, Shaojun Wang, Wei Wang, Wen Wang, Ye-Yi Wang, Wayne Ward, Taro Watanabe, Andy Way, Nick Webb, Bonnie Webber, Ralph Weischedel, Edward Whittaker, Richard Wicentowski, Yorick Wilks, Theresa Wilson, Shuly Wintner, Dekai Wu, Xiaoyun Wu;

Aris Xanthos, Fei Xia, Eric Xing, Feiyu Xu, Peng Xu;

Scott Wen-tau Yih;

Fabio Zanzotto, Richard Zens, ChengXiang Zhai, Hao Zhang, Tong Zhang, Ying Zhang, Shubin Zhao, Guoding Zhou, Liang Zhou, Jerry Zhu, Michael Zock, Jelle Zuidema

CoNLL Shared Task Reviewers:

Jason Baldridge, Sabine Buchholz, James Clarke, Gülşen Eryiğit, Kilian Evang, Johan Hall, Julia Hockenmaier, Yuval Krymolowski, Sandra Kübler, Erwin Marsi, Ryan McDonald, Beáta Megyesi, Jens Nilsson, Joakim Nivre, Sebastian Riedel, Yannick Versley, Alexander Yeh, Deniz Yuret

Table of Contents

Conference Program Overview

Thursday, June 28, 2007

9:00–10:45	Session 1: Plenary Session
10:45–11:15	Morning Break
11:15–12:30	Sessions 2a and 2b
12:30–14:00	Lunch
14:00–15:40	Sessions 3a and 3b
15:40–16:00	Afternoon Break
16:00–18:30	Session 4: All Posters

Friday, June 29, 2007

9:00–10:40	Sessions 5a and 5b
10:40–11:15	Morning Break
11:15–12:30	Sessions 6a and 6b
12:30–14:00	Lunch
14:00–15:40	Sessions 7a and 7b
15:40–16:00	Afternoon Break
16:00–18:30	Session 8: All Posters

Saturday, June 30, 2007

9:00–10:00	Session 9: Plenary Session
10:00–10:50	Sessions 10a, 10b, and 10c
10:50–11:15	Morning Break
11:15–12:30	Sessions 11a, 11b, and 11c
12:30–14:00	Lunch
14:00–15:40	Sessions 12a, 12b, and 12c
15:40–16:15	Afternoon Break
16:15–17:30	Sessions 13a, 13b, and 13c
17:30	Concluding Session

Conference Program

Thursday, June 28, 2007

Session 1: Plenary Session

9:00–9:10 Opening Remarks

9:10–10:10 Invited Talk: *Baby Bayesians? Evidence for Statistical Hypothesis Selection in Infant Language Learning*
LouAnn Gerken, University of Arizona

10:15–10:45 *Modelling Compression with Discourse Constraints*
James Clarke and Mirella Lapata

Session 2a: Question Answering

11:15–11:40 *Using Semantic Roles to Improve Question Answering*
Dan Shen and Mirella Lapata

11:40–12:05 *What is the Jeopardy Model? A Quasi-Synchronous Grammar for QA*
Mengqiu Wang, Noah A. Smith and Teruko Mitamura

12:05–12:30 *Learning Unsupervised SVM Classifier for Answer Selection in Web Question Answering*
Youzheng Wu, Ruiqiang Zhang, Xinhui Hu and Hideki Kashioka

Session 2b: Machine Translation

11:15–11:40 *Improving Word Alignment with Bridge Languages*
Shankar Kumar, Franz J. Och and Wolfgang Macherey

11:40–12:05 *Getting the Structure Right for Word Alignment: LEAF*
Alexander Fraser and Daniel Marcu

12:05–12:30 *Improving Statistical Machine Translation Using Word Sense Disambiguation*
Marine Carpuat and Dekai Wu

Thursday, June 28, 2007 (continued)

Session 3a: Generation, Summarization, and Discourse

14:00–14:25 *Large Margin Synchronous Generation and its Application to Sentence Compression*
Trevor Cohn and Mirella Lapata

14:25–14:50 *Incremental Text Structuring with Online Hierarchical Ranking*
Erdong Chen, Benjamin Snyder and Regina Barzilay

14:50–15:15 *Automatically Identifying the Arguments of Discourse Connectives*
Ben Wellner and James Pustejovsky

15:15–15:40 *Incremental Generation of Plural Descriptions: Similarity and Partitioning*
Albert Gatt and Kees van Deemter

Session 3b: Parsing

14:00–14:25 *A Comparative Evaluation of Deep and Shallow Approaches to the Automatic Detection of Common Grammatical Errors*
Joachim Wagner, Jennifer Foster and Josef van Genabith

14:25–14:50 *Characterizing the Errors of Data-Driven Dependency Parsing Models*
Ryan McDonald and Joakim Nivre

14:50–15:15 *Probabilistic Models of Nonprojective Dependency Trees*
David A. Smith and Noah A. Smith

15:15–15:40 *Structured Prediction Models via the Matrix-Tree Theorem*
Terry Koo, Amir Globerson, Xavier Carreras and Michael Collins

Thursday, June 28, 2007 (continued)

Session 4: All Posters (16:00–18:30)

Using Foreign Inclusion Detection to Improve Parsing Performance
Beatrice Alex, Amit Dubey and Frank Keller

LEDIR: An Unsupervised Algorithm for Learning Directionality of Inference Rules
Rahul Bhagat, Patrick Pantel and Eduard Hovy

Modelling Polysemy in Adjective Classes by Multi-Label Classification
Gemma Boleda, Sabine Schulte im Walde and Toni Badia

Improving Query Spelling Correction Using Web Search Results
Qing Chen, Mu Li and Ming Zhou

Towards Robust Unsupervised Personal Name Disambiguation
Ying Chen and James Martin

Compressing Trigram Language Models With Golomb Coding
Kenneth Church, Ted Hart and Jianfeng Gao

Joint Morphological and Syntactic Disambiguation
Shay B. Cohen and Noah A. Smith

Unsupervised Part-of-Speech Acquisition for Resource-Scarce Languages
Sajib Dasgupta and Vincent Ng

Semi-Supervised Classification for Extracting Protein Interaction Sentences using Dependency Parsing
Gunes Erkan, Arzucan Ozgur and Dragomir R. Radev

A Sequence Alignment Model Based on the Averaged Perceptron
Dayne Freitag and Shahram Khadivi

Instance Based Lexical Entailment for Ontology Population
Claudio Giuliano and Alfio Gliozzo

Recovering Non-Local Dependencies for Chinese
Yuqing Guo, Haifeng Wang and Josef van Genabith

Thursday, June 28, 2007 (continued)

Session 4: All Posters (16:00–18:30) (continued)

Exploiting Multi-Word Units in History-Based Probabilistic Generation
Deirdre Hogan, Conor Cafferkey, Aoife Cahill and Josef van Genabith

Hierarchical System Combination for Machine Translation
Fei Huang and Kishore Papineni

Using RBMT Systems to Produce Bilingual Corpus for SMT
Xiaoguang Hu, Haifeng Wang and Hua Wu

Why Doesn't EM Find Good HMM POS-Taggers?
Mark Johnson

Probabilistic Coordination Disambiguation in a Fully-Lexicalized Japanese Parser
Daisuke Kawahara and Sadao Kurohashi

A New Perceptron Algorithm for Sequence Labeling with Non-Local Features
Jun'ichi Kazama and Kentaro Torisawa

Extending a Thesaurus in the Pan-Chinese Context
Oi Yee Kwong and Benjamin K. Tsou

Low-Quality Product Review Detection in Opinion Summarization
Jingjing Liu, Yunbo Cao, Chin-Yew Lin, Yalou Huang and Ming Zhou

Improving Statistical Machine Translation Performance by Training Data Selection and Optimization
Yajuan Lu, Jin Huang and Qun Liu

Topic Segmentation with Hybrid Document Indexing
Irina Matveeva and Gina-Anne Levow

Syntactic Re-Alignment Models for Machine Translation
Jonathan May and Kevin Knight

Detecting Compositionality of Verb-Object Combinations using Selectional Preferences
Diana McCarthy, Sriram Venkatapathy and Aravind Joshi

Explorations in Automatic Book Summarization
Rada Mihalcea and Hakan Ceylan

Thursday, June 28, 2007 (continued)

Session 4: All Posters (16:00–18:30) (continued)

Thursday, June 28, 2007 (continued)

Session 4: All Posters (16:00–18:30) (continued)

Friday, June 29, 2007

Session 5a: Semantics

9:00–9:25 *Generating Lexical Analogies Using Dependency Relations*
Andy Chiu, Pascal Poupart and Chrysanne DiMarco

9:25–9:50 *Cross-Lingual Distributional Profiles of Concepts for Measuring Semantic Distance*
Saif Mohammad, Iryna Gurevych, Graeme Hirst and Torsten Zesch

9:50–10:15 *Lexical Semantic Relatedness with Random Graph Walks*
Thad Hughes and Daniel Ramage

10:15–10:40 *Experimental Evaluation of LTAG-Based Features for Semantic Role Labeling*
Yudong Liu and Anoop Sarkar

Session 5b: Parsing

9:00–9:25 *Japanese Dependency Analysis Using the Ancestor-Descendant Relation*
Akihiro Tamura, Hiroya Takamura and Manabu Okumura

9:25–9:50 *A Discriminative Learning Model for Coordinate Conjunctions*
Masashi Shimbo and Kazuo Hara

9:50–10:15 *Recovery of Empty Nodes in Parse Structures*
Denis Filimonov and Mary Harper

10:15–10:40 *Treebank Annotation Schemes and Parser Evaluation for German*
Ines Rehbein and Josef van Genabith

Friday, June 29, 2007 (continued)

Session 6a: Document Analysis

11:15–11:40 *Semi-Markov Models for Sequence Segmentation*
Qinfeng Shi, Yasemin Altun, Alex Smola and S.V.N. Vishwanathan

11:40–12:05 *A Graph-Based Approach to Named Entity Categorization in Wikipedia Using Conditional Random Fields*
Yotaro Watanabe, Masayuki Asahara and Yuji Matsumoto

12:05–12:30 *MavenRank: Identifying Influential Members of the US Senate Using Lexical Centrality*
Anthony Fader, Dragomir R. Radev, Michael H. Crespin, Burt L. Monroe, Kevin M. Quinn and Michael Colaresi

Session 6b: Grammar Learning

11:15–11:40 *Bootstrapping Feature-Rich Dependency Parsers with Entropic Priors*
David A. Smith and Jason Eisner

11:40–12:05 *Online Learning of Relaxed CCG Grammars for Parsing to Logical Form*
Luke Zettlemoyer and Michael Collins

12:05–12:30 *The Infinite PCFG Using Hierarchical Dirichlet Processes*
Percy Liang, Slav Petrov, Michael Jordan and Dan Klein

Friday, June 29, 2007 (continued)

Session 7a: Information Extraction

14:00–14:25 *Exploiting Wikipedia as External Knowledge for Named Entity Recognition*
Jun'ichi Kazama and Kentaro Torisawa

14:25–14:50 *Large-Scale Named Entity Disambiguation Based on Wikipedia Data*
Silviu Cucerzan

14:50–15:15 *Effective Information Extraction with Semantic Affinity Patterns and Relevant Regions*
Siddharth Patwardhan and Ellen Riloff

15:15–15:40 *Tree Kernel-Based Relation Extraction with Context-Sensitive Structured Parse Tree Information*
GuoDong Zhou, Min Zhang, DongHong Ji and QiaoMing Zhu

Session 7b: Machine Translation

14:00–14:25 *Chinese Syntactic Reordering for Statistical Machine Translation*
Chao Wang, Michael Collins and Philipp Koehn

14:25–14:50 *Binarizing Syntax Trees to Improve Syntax-Based Machine Translation Accuracy*
Wei Wang, Kevin Knight and Daniel Marcu

14:50–15:15 *What Can Syntax-Based MT Learn from Phrase-Based MT?*
Steve DeNeefe, Kevin Knight, Wei Wang and Daniel Marcu

15:15–15:40 *Online Large-Margin Training for Statistical Machine Translation*
Taro Watanabe, Jun Suzuki, Hajime Tsukada and Hideki Isozaki

Session 8: All Posters (16:00–18:30)

Consult the list of poster titles under Session 4.

Saturday, June 30, 2007

Session 9: Plenary Session

9:00–10:00 Invited Talk: *Hashing, Sketching, and Other Approximate Algorithms for High-Dimensional Data*
Piotr Indyk, Massachusetts Institute of Technology

Session 10a: Machine Learning (supervised classifiers)

10:00–10:25 *Scalable Term Selection for Text Categorization*
Jingyang Li and Maosong Sun

10:25–10:50 *Active Learning for Word Sense Disambiguation with Methods for Addressing the Class Imbalance Problem*
Jingbo Zhu and Eduard Hovy

Session 10b: Machine Learning (sequential models)

10:00–10:25 *Semi-Supervised Structured Output Learning Based on a Hybrid Generative and Discriminative Approach*
Jun Suzuki, Akinori Fujino and Hideki Isozaki

10:25–10:50 *Finding Good Sequential Model Structures using Output Transformations*
Edward Loper

Session 10c: Information Retrieval

10:00–10:25 *A Statistical Language Modeling Approach to Lattice-Based Spoken Document Retrieval*
Tee Kiah Chia, Haizhou Li and Hwee Tou Ng

10:25–10:50 *Learning Noun Phrase Query Segmentation*
Shane Bergsma and Qin Iris Wang

Saturday, June 30, 2007 (continued)

Session 11a: Information Extraction

11:15–11:40 *Bootstrapping Information Extraction from Field Books*
Sander Canisius and Caroline Sporleder

11:40–12:05 *Extracting Data Records from Unstructured Biomedical Full Text*
Donghui Feng, Gully Burns and Eduard Hovy

12:05–12:30 *Multiple Alignment of Citation Sentences with Conditional Random Fields and Posterior Decoding*
Ariel Schwartz, Anna Divoli and Marti Hearst

Session 11b: Machine Translation

11:15–11:40 *Large Language Models in Machine Translation*
Thorsten Brants, Ashok C. Popat, Peng Xu, Franz J. Och and Jeffrey Dean

11:40–12:05 *Factored Translation Models*
Philipp Koehn and Hieu Hoang

12:05–12:30 *Translating Unknown Words by Analogical Learning*
Philippe Langlais and Alexandre Patry

Session 11c: Phonetics and Phonology

11:15–11:40 *A Probabilistic Approach to Diachronic Phonology*
Alexandre Bouchard, Percy Liang, Thomas Griffiths and Dan Klein

11:40–12:05 *Learning Structured Models for Phone Recognition*
Slav Petrov, Adam Pauls and Dan Klein

12:05–12:30 *Inducing Search Keys for Name Filtering*
L. Karl Branting

Saturday, June 30, 2007 (continued)

Session 12a: CoNLL Shared Task Session (dependency parsing)

14:00–14:15 *The CoNLL 2007 Shared Task on Dependency Parsing*
Joakim Nivre, Johan Hall, Sandra Kübler, Ryan McDonald, Jens Nilsson, Sebastian Riedel and Deniz Yuret

14:15–14:30 *Single Malt or Blended? A Study in Multilingual Parser Optimization*
Johan Hall, Jens Nilsson, Joakim Nivre, Gülsen Eryigit, Beáta Megyesi, Mattias Nilsson and Markus Saers

14:30–14:45 *Probabilistic Parsing Action Models for Multi-Lingual Dependency Parsing*
Xiangyu Duan, Jun Zhao and Bo Xu

14:45–15:00 *Fast and Robust Multilingual Dependency Parsing with a Generative Latent Variable Model*
Ivan Titov and James Henderson

15:00–15:15 *Multilingual Dependency Parsing Using Global Features*
Tetsuji Nakagawa

15:15–15:30 *Experiments with a Higher-Order Projective Dependency Parser*
Xavier Carreras

15:30–15:45 *Log-Linear Models of Non-Projective Trees, k-best MST Parsing and Tree-Ranking*
Keith Hall, Jiri Havelka and David A. Smith

Saturday, June 30, 2007 (continued)

Session 12b: Machine Translation

14:00–14:25 *Improving Translation Quality by Discarding Most of the Phrasetable*
Howard Johnson, Joel Martin, George Foster and Roland Kuhn

14:25–14:50 *Hierarchical Phrase-Based Translation with Suffix Arrays*
Adam Lopez

14:50–15:15 *An Empirical Study on Computing Consensus Translations from Multiple Machine Translation Systems*
Wolfgang Macherey and Franz J. Och

15:15–15:40 *Learning to Find English to Chinese Transliterations on the Web*
Jian-Cheng Wu and Jason S. Chang

Session 12c: Word Senses

14:00–14:25 *Learning to Merge Word Senses*
Rion Snow, Sushant Prakash, Daniel Jurafsky and Andrew Y. Ng

14:25–14:50 *Improving Word Sense Disambiguation Using Topic Features*
Junfu Cai, Wee Sun Lee and Yee Whye Teh

14:50–15:15 *A Topic Model for Word Sense Disambiguation*
Jordan Boyd-Graber, David Blei and Xiaojin Zhu

15:15–15:40 *Validation and Evaluation of Automatically Acquired Multiword Expressions for Grammar Engineering*
Aline Villavicencio, Valia Kordoni, Yi Zhang, Marco Idiart and Carlos Ramisch

Saturday, June 30, 2007 (continued)

Session 13a: CoNLL Shared Task Session (dependency parsing)

16:15–16:30 *Dependency Parsing and Domain Adaptation with LR Models and Parser Ensembles*
Kenji Sagae and Jun'ichi Tsujii

16:30–16:45 *Frustratingly Hard Domain Adaptation for Dependency Parsing*
Mark Dredze, John Blitzer, Partha Pratim Talukdar, Kuzman Ganchev, João Graca and Fernando Pereira

16:45–17:15 Analysis: Sandra Kübler, Ryan McDonald

17:15–17:30 Discussion

Session 13b: Sentiment

16:15–16:40 *Crystal: Analyzing Predictive Opinions on the Web*
Soo-Min Kim and Eduard Hovy

16:40–17:05 *Extracting Aspect-Evaluation and Aspect-Of Relations in Opinion Mining*
Nozomi Kobayashi, Kentaro Inui and Yuji Matsumoto

17:05–17:30 *Building Lexicon for Sentiment Analysis from Massive Collection of HTML Documents*
Nobuhiro Kaji and Masaru Kitsuregawa

Session 13c: Tagging

16:15–16:40 *Determining Case in Arabic: Learning Complex Linguistic Behavior Requires Complex Linguistic Features*
Nizar Habash, Ryan Gabbard, Owen Rambow, Seth Kulick and Mitch Marcus

16:40–17:05 *Mandarin Part-of-Speech Tagging and Discriminative Reranking*
Zhongqiang Huang, Mary Harper and Wen Wang

17:05–17:30 *Building Domain-Specific Taggers without Annotated (Domain) Data*
John Miller, Manabu Torii and K. Vijay-Shanker

Concluding Session

17:30 Closing Remarks

Additional CoNLL Shared Task Papers (dependency parsing)

Modelling Compression with Discourse Constraints

Abstract

Sentence compression holds promise for many applications ranging from summarisation to subtitle generation and subtitle generation. The task is typically performed on isolated sentences without taking the surrounding context into account, even though most applications would operate over entire documents. In this paper we present a discourse informed model which is capable of producing document compressions that are coherent and informative. Our model is inspired by theories of local coherence and formulated within the framework of Integer Linear Programming. Experimental results show significant improvements over a state-of-the-art discourse agnostic approach.

1 Introduction

The computational treatment of sentence compression has recently attracted much attention in the literature. The task can be viewed as producing a summary of a single sentence that retains the most important information and remains grammatically correct (Jing 2000). Sentence compression is commonly expressed as a word deletion problem: given an input sentence of words $W = w_1, w_2, \ldots, w_n$, the aim is to produce a compression by removing any subset of these words (Knight and Marcu 2002).

Sentence compression can potentially benefit many applications. For example, in summarisation, a compression mechanism could improve the conciseness of the generated summaries (Jing 2000; Lin 2003). Sentence compression could be also used to automatically generate subtitles for television programs; the transcripts cannot usually be used verbatim due to the rate of speech being too high (Vandeghinste and Pan 2004). Other applications include compressing text to be displayed on small screens (Corston-Oliver 2001) such as mobile phones or PDAs, and producing audio scanning devices for the blind (Grefenstette 1998).

Most work to date has focused on a rather simple formulation of sentence compression that does not allow any rewriting operations, besides word removal. Moreover, compression is performed on isolated sentences without taking into account their surrounding context. An advantage of this simple view is that it renders sentence compression amenable to a variety of learning paradigms ranging from instantiations of the noisy-channel model (Galley and McKeown 2007; Knight and Marcu 2002; Turner and Charniak 2005) to Integer Linear Programming (Clarke and Lapata 2006a) and large-margin online learning (McDonald 2006).

In this paper we take a closer look at one of the simplifications associated with the compression task, namely that sentence reduction can be realised in isolation without making use of discourse-level information. This is clearly not true — professional abstracters often rely on contextual cues while creating summaries (Endres-Niggemeyer 1998). Furthermore, determining what information is important in a sentence is influenced by a variety of contextual factors such as the discourse topic, whether the sentence introduces new entities or events that have not been mentioned before, and the reader's background knowledge.

The simplification is also at odds with most applications of sentence compression which aim to create a shorter document rather than a single sentence. The resulting document must not only be grammat-

Proceedings of the 2007 Joint Conference on Empirical Methods in Natural Language Processing and Computational Natural Language Learning, pp. 1–11, Prague, June 2007. ©2007 Association for Computational Linguistics

ical but also coherent if it is to function as a replacement for the original. However, this cannot be guaranteed without knowing how the discourse progresses from sentence to sentence. To give a simple example, a contextually aware compression system could drop a word or phrase from the current sentence, simply because it is not mentioned anywhere else in the document and is therefore deemed unimportant. Or it could decide to retain it for the sake of topic continuity.

We are interested in creating a compression model that is appropriate for documents and sentences. To this end, we assess whether discourse-level information is helpful. Our analysis is informed by two popular models of discourse, Centering Theory (Grosz et al. 1995) and lexical chains (Morris and Hirst 1991). Both approaches model *local coherence* — the way adjacent sentences bind together to form a larger discourse. Our compression model is an extension of the integer programming formulation proposed by Clarke and Lapata (2006a). Their approach is conceptually simple: it consists of a scoring function coupled with a small number of syntactic and semantic constraints. Discourse-related information can be easily incorporated in the form of additional constraints. We employ our model to perform sentence compression throughout a whole document (by compressing sentences sequentially) and evaluate whether the resulting text is understandable and informative using a question-answering task. Our method yields significant improvements over a discourse agnostic state-of-the-art compression model (McDonald 2006).

2 Related Work

Sentence compression has been extensively studied across different modelling paradigms and has received both generative and discriminative formulations. Most generative approaches (Galley and McKeown 2007; Knight and Marcu 2002; Turner and Charniak 2005) are instantiations of the noisy-channel model, whereas discriminative formulations include decision-tree learning (Knight and Marcu 2002), maximum entropy (Riezler et al. 2003), support vector machines (Nguyen et al. 2004), and large-margin learning (McDonald 2006). These models are trained on a parallel corpus of long *source* sentences and their *target* compressions. Using a rich feature set derived from parse trees, the models learn either which constituents to delete or which words to place adjacently in the compression output. Relatively few approaches dispense with the parallel corpus and generate compressions in an unsupervised manner using either a scoring function (Clarke and Lapata 2006a; Hori and Furui 2004) or compression rules that are approximated from a non-parallel corpus such as the Penn Treebank (Turner and Charniak 2005).

Our work differs from previous approaches in two key respects. First, we present a compression model that is contextually aware; decisions on whether to remove or retain a word (or phrase) are informed by its discourse properties (e.g., whether it introduces a new topic, whether it is semantically related to the previous sentence). Second, we apply our compression model to entire documents rather than isolated sentences. This is more in the spirit of real-world applications where the goal is to generate a condensed and coherent text. Previous work on summarisation has also utilised discourse information (e.g., Barzilay and Elhadad 1997; Daumé III and Marcu 2002; Marcu 2000; Teufel and Moens 2002). However, its application to document compression is novel to our knowledge.

3 Discourse Representation

Obtaining an appropriate representation of discourse is the first step towards creating a compression model that exploits contextual information. In this work we focus on the role of local coherence as this is prerequisite for maintaining global coherence. Ideally, we would like our compressed document to maintain the discourse flow of the original. For this reason, we automatically annotate the source document with discourse-level information which is subsequently used to inform our compression procedure. We first describe our algorithms for obtaining discourse annotations and then present our compression model.

3.1 Centering Theory

Centering Theory (Grosz et al. 1995) is an entity-orientated theory of local coherence and salience. Although an utterance in discourse may contain several entities, it is assumed that a *single entity* is salient or "centered", thereby representing the current focus. One of the main claims underlying centering is that discourse segments in which successive utterances contain common centers are more coherent than segments where the center repeatedly changes.

Each utterance U_i in a discourse segment has a list of *forward-looking centers*, $C_f(U_i)$ and a *unique backward-looking center*, $C_b(U_i)$. $C_f(U_i)$ represents a ranking of the entities invoked by U_i according to their salience. The C_b of the current utterance U_i, is the highest-ranked element in $C_f(U_{i-1})$ that is also in U_i. The C_b thus links U_i to the previous discourse, but it does so *locally* since $C_b(U_i)$ is chosen from U_{i-1}.

Centering Algorithm So far we have presented centering without explicitly stating how the concepts "utterance", "entities" and "ranking" are instantiated. A great deal of research has been devoted into fleshing these out and many different instantiations have been developed in the literature (see Poesio et al. 2004 for details). Since our aim is to identify centers in discourse automatically, our parameter choice is driven by two considerations, robustness and ease of computation.

We therefore follow previous work (e.g., Miltsakaki and Kukich 2000) in assuming that the unit of an utterance is the sentence (i.e., a main clause with accompanying subordinate and adjunct clauses). This is in line with our compression task which also operates over sentences. We determine which entities are invoked by a sentence using two methods. First, we perform named entity identification and coreference resolution on each document using LingPipe[1], a publicly available system. Named entities and all remaining nouns are added to the C_f list. Entity matching between sentences is required to determine the C_b of a sentence. This is done using the named entity's unique identifier (as provided by LingPipe) or by the entity's surface form in the case of nouns not classified as named entities.

Entities are ranked according to their grammatical roles; subjects are ranked more highly than objects, which are in turn ranked higher than other grammatical roles (Grosz et al. 1995); ties are broken using left-to-right ordering of the grammatical roles in the sentence (Tetreault 2001). We identify grammatical roles with RASP (Briscoe and Carroll 2002). Formally, our centering algorithm is as follows (where U_i corresponds to sentence i):

1. Extract entities from U_i.
2. Create $C_f(U_i)$ by ranking the entities in U_i according to their grammatical role (subjects $>$ objects $>$ others).
3. Find the highest ranked entity in $C_f(U_{i-1})$ which occurs in $C_f(U_i)$, set the entity to be $C_b(U_i)$.

The above procedure involves several automatic steps (named entity recognition, coreference resolution, identification of grammatical roles) and will unavoidably produce some noisy annotations. So, there is no guarantee that the right C_b will be identified or that all sentences will be marked with a C_b. The latter situation also occurs in passages that contain abrupt changes in topic. In such cases, none of the entities realised in U_i will occur in $C_f(U_{i-1})$. Rather than accept that discourse information may be absent in a sentence, we turn to lexical chains as an alternative means of capturing topical content within a document.

3.2 Lexical Chains

Lexical cohesion refers to the degree of semantic relatedness observed among lexical items in a document. The term was coined by Halliday and Hasan (1976) who observed that coherent documents tend to have more related terms or phrases than incoherent ones. A number of linguistic devices can be used to signal cohesion; these range from repetition, to synonymy, hyponymy and meronymy. Lexical chains are a representation of lexical cohesion as sequences of semantically related words (Morris and Hirst 1991) and provide a useful means for describing the topic flow in discourse. For instance, a document with many different lexical chains will probably contain several topics. And main topics will tend to be represented by dense and long chains. Words participating in such chains are important for our compression task — they reveal what the document is about — and in all likelihood should not be deleted.

Lexical Chains Algorithm Barzilay and Elhadad (1997) describe a technique for text summarisation based on lexical chains. Their algorithm uses WordNet to build chains of nouns (and noun compounds). These are ranked heuristically by a score based on their length and homogeneity. A summary is then produced by extracting sentences corresponding to

[1] LingPipe can be downloaded from `http://www.alias-i.com/lingpipe/`.

strong chains, i.e., chains whose score is two standard deviations above the average score.

Like Barzilay and Elhadad (1997), we wish to determine which lexical chains indicate the most prevalent discourse topics. Our assumption is that terms belonging to these chains are indicative of the document's main focus and should therefore be retained in the compressed output. Barzilay and Elhadad's scoring function aims to identify sentences (for inclusion in a summary) that have a high concentration of chain members. In contrast, we are interested in chains that span several sentences. We thus score chains according to the number of sentences their terms occur in. For example, the chain $\{house_3, home_3, loft_3, house_5\}$ (where $word_i$ denotes *word* occurring in sentence *i*) would be given a score of two as the terms only occur in two sentences. We assume that a chain signals a prevalent discourse topic if it occurs throughout more sentences than the average chain. The scoring algorithm is outlined more formally below:

1. Compute the lexical chains for the document.
2. $Score(Chain) = Sentences(Chain)$.
3. Discard chains if $Score(Chain) < Avg(Score)$.
4. Mark terms from the remaining chains as being the focus of the document.

We use the method of Galley and McKeown (2003) to compute lexical chains for each document.[2] This is an improved version of Barzilay and Elhadad's (1997) original algorithm.

Before compression takes place, all documents are pre-processed using the centering and lexical chain algorithms described above. In each sentence we mark the center $C_b(U_i)$ if one exists. Words (or phrases) that are present in the current sentence and function as the center in the next sentence $C_b(U_{i+1})$ are also flagged. Finally, words are marked if they are part of a prevalent chain. An example of our discourse annotation is given in Figure 1.

Bad weather dashed hopes of attempts to halt the flow$_1$ during what was seen as a lull in the lava's momentum. Experts say that even if the eruption stopped today$_2$, the pressure of lava piled up behind for six miles$_3$ would bring debris cascading down on to the town anyway. Some estimate the volcano is pouring out one million tons of debris a day$_2$, at a rate$_1$ of 15ft$_3$ per second$_2$, from a fissure that opened in mid-December.
The Italian Army yesterday$_2$ detonated 400lb of dynamite 3,500 feet up Mount Etna's slopes.

Figure 1: Excerpt of document from our test set with discourse annotations. Centers are in double boxes; terms occurring in lexical chains are in oval boxes. Words with the same subscript are members of the same chain (e.g., *today*, *day*, *second*, *yesterday*)

4 The Compression Model

Our model is an extension of the approach put forward in Clarke and Lapata (2006a). Their work tackles sentence compression as an optimisation problem. Given a long sentence, a compression is formed by retaining the words that maximise a scoring function. The latter is essentially a language model coupled with a few constraints ensuring that the resulting output is grammatical. The language model and the constraints are encoded as linear inequalities whose solution is found using Integer Linear Programming (ILP, Vanderbei 2001; Winston and Venkataramanan 2003).

We selected this model for several reasons. First it does not require a parallel corpus and thus can be ported across domains and text genres, whilst delivering state-of-the-art results (see Clarke and Lapata 2006a for details). Second, discourse-level information can be easily incorporated by augmenting the constraint set. This is not the case for other approaches (e.g., those based on the noisy channel model) where compression is modelled by grammar rules indicating which constituents to delete in a syntactic context. Third, the ILP framework delivers a globally optimal solution by searching over the entire compression space[3] without employing heuristics or approximations during decoding.

We begin by recapping the formulation of Clarke and Lapata (2006a). Let $W = w_1, w_2, \ldots, w_n$ denote a sentence for which we wish to generate a compression. A set of binary decision variables represent whether each word w_i should be included in the

[2] The software is available from `http://www1.cs.columbia.edu/~galley/`.

[3] For a sentence of length *n*, there are 2^n compressions.

compression or not. Let:

$$y_i = \begin{cases} 1 & \text{if } w_i \text{ is in the compression} \\ 0 & \text{otherwise} \end{cases} \quad \forall i \in [1 \dots n]$$

A trigram language model forms the backbone of the compression model. The language model is formulated as an integer program with the introduction of extra decision variables indicating which *word sequences* should be retained or dropped from the compression. Let:

$$p_i = \begin{cases} 1 \text{ if } w_i \text{ starts the compression} \\ 0 \text{ otherwise} \end{cases} \forall i \in [1 \dots n]$$

$$q_{ij} = \begin{cases} 1 \text{ if sequence } w_i, w_j \text{ ends} \\ \quad \text{the compression} & \forall i \in [1 \dots n-1] \\ 0 \text{ otherwise} & \forall j \in [i+1 \dots n] \end{cases}$$

$$x_{ijk} = \begin{cases} 1 \text{ if sequence } w_i, w_j, w_k & \forall i \in [1 \dots n-2] \\ \quad \text{is in the compression} & \forall j \in [i+1 \dots n-1] \\ 0 \text{ otherwise} & \forall k \in [j+1 \dots n] \end{cases}$$

The objective function is expressed in Equation (1). It is the sum of all possible trigrams multiplied by the appropriate decision variable. The objective function also includes a significance score for each word multiplied by the decision variable for that word (see the last summation term in (1)). This score highlights important content words in a sentence and is defined in Section 4.1.

$$\begin{aligned} \max z \quad = \quad & \sum_{i=1}^{n} p_i \cdot P(w_i|\text{start}) \\ & + \sum_{i=1}^{n-2} \sum_{j=i+1}^{n-1} \sum_{k=j+1}^{n} x_{ijk} \cdot P(w_k|w_i, w_j) \\ & + \sum_{i=0}^{n-1} \sum_{j=i+1}^{n} q_{ij} \cdot P(\text{end}|w_i, w_j) \\ & + \sum_{i=1}^{n} y_i \cdot I(w_i) \qquad (1) \end{aligned}$$

subject to:

$$y_i, p_i, q_{ij}, x_{ijk} = 0 \text{ or } 1 \qquad (2)$$

A set of *sequential* constraints[4] are added to the problem to only allow results which combine valid trigrams.

4.1 Significance Score

The significance score is an attempt at capturing the gist of a sentence. It gives more weight to content words that appear in the deepest level of embedding in the syntactic tree representing the source sentence:

$$I(w_i) = \frac{l}{N} \cdot f_i \log \frac{F_a}{F_i} \qquad (3)$$

The score is computed over a large corpus where w_i is a content word (i.e., a noun or verb), f_i and F_i are the frequencies of w_i in the document and corpus respectively, and F_a is the sum of all content words in the corpus. l is the number of clause constituents above w_i, and N is the deepest level of embedding.

4.2 Sentential Constraints

The model also contains a small number of sentence-level constraints. Their aim is to preserve the meaning and structure of the original sentence as much as possible. The majority of constraints revolve around modification and argument structure and are defined over parse trees or grammatical relations. For example, the following constraint template disallows the inclusion of modifiers (e.g., nouns, adjectives) without their head words:

$$\begin{gathered} y_i - y_j \geq 0 \qquad (4) \\ \forall i, j : w_j \text{ modifies } w_i \end{gathered}$$

Other constraints force the presence of modifiers when the head is retained in the compression. This way, it is ensured that negation will be preserved in the compressed output:

$$\begin{gathered} y_i - y_j = 0 \qquad (5) \\ \forall i, j : w_j \text{ modifies } w_i \ \wedge \ w_j = \text{not} \end{gathered}$$

Argument structure constraints make sure that the resulting compression has a canonical argument structure. For instance a constraint ensures that if a verb is present in the compression then so are its arguments:

$$\begin{gathered} y_i - y_j = 0 \qquad (6) \\ \forall i, j : w_j \in \text{subject/object of verb } w_i \end{gathered}$$

Finally, Clarke and Lapata (2006a) propose one discourse constraint which forces the system to preserve personal pronouns in the compressed output:

$$\begin{gathered} y_i = 1 \qquad (7) \\ \forall i : w_i \in \text{ personal pronouns} \end{gathered}$$

[4] We have omitted sequential constraints due to space limitations. The full details are given in Clarke and Lapata (2006a).

4.3 Discourse Constraints

In addition to the constraints described above, our model includes constraints relating to the centering and lexical chains representations discussed in Section 3. Recall that after some pre-processing, each sentence is marked with: its own center $C_b(U_i)$, the center $C_b(U_{i+1})$ of the sentence following it and words that are members of high scoring chains corresponding to the document's focus. We introduce two new types of constraints based on these additional knowledge sources.

The first constraint is the centering constraint which operates over adjacent sentences. It ensures that the C_b identified in the source sentence is retained in the target compression. If present, the entity realised as the C_b in the following sentence is also retained:

$$y_i = 1 \qquad (8)$$
$$\forall i : w_i \in \{C_b(U_i), C_b(U_{i+1})\}$$

Consider for example the discourse in Figure 1. The constraints generated from Equation (8) will require the compression to retain *lava* in the first two sentences and *debris* in sentences two and three.

We also add a lexical chain constraint. This applies only to nouns which are members of prevalent chains:

$$y_i = 1 \qquad (9)$$
$$\forall i : w_i \in \text{document focus lexical chain}$$

This constraint is complementary to the centering constraint; the sentences it applies to do not have to be adjacent and the entities under consideration are not restricted to a specific syntactic role (e.g., subject or object). See for instance the words *flow* and *rate* in Figure 1 which are members of the same chain (marked with subscript one). According to constraint (9) both words must be included in the compressed document.

The constraints just described ensure that the compressed document will retain the discourse flow of the original and will preserve terms indicative of important topics. We argue that these constraints will additionally benefit sentence-level compression, as words which are not signalled as discourse relevant can be dropped.

4.4 Applying the Constraints

Our compression system is given a (sentence separated) document as input. The ILP model just presented is then applied sequentially to all sentences to generate a compressed version of the original. We thus create and solve an ILP for every sentence.[5] In the formulation of Clarke and Lapata (2006a) a significance score (see Section 4.1) highlights which nouns and verbs to include in the compression. As far as nouns are concerned, our discourse constraints perform a similar task. Thus, when a sentence contains discourse annotations, we are inclined to trust them more and only calculate the significance score for verbs.

During development it was observed that applying all discourse constraints simultaneously (see Equations (7)–(9)) results in relatively long compressions. To counter this, we employ these constraints using a back-off strategy that relies on progressively less reliable information. Our back-off model works as follows: if centering information is present, we apply the appropriate constraints (Equation (8)). If no centers are present, we back-off to the lexical chain information using Equation (9), and in the absence of the latter we back-off to the pronoun constraint (Equation (7)). Finally, if discourse information is entirely absent from the sentence, we default to the significance score. Sentential constraints (see Section 4.2) are applied throughout irrespectively of discourse constraints. In our test data (see Section 5 for details), the centering constraint was used in 68.6% of the sentences. The model backed off to lexical chains for 13.7% of the test sentences, whereas the pronoun constraint was applied in 8.5%. Finally, the noun and verb significance score was used on the remaining 9.2%. An example of our system's output for the text in Figure 1 is given in Figure 2.

5 Experimental Set-up

In this section we present our experimental set-up. We briefly introduce the model used for comparison with our approach and give details regarding our compression corpus and parameter estimation. Finally, we describe our evaluation methodology.

[5] We use the publicly available *lp_solve* solver (`http://www.geocities.com/lpsolve/`).

> Bad weather dashed hopes to halt the flow during what was seen as lull in lava's momentum. Experts say that even if eruption stopped, the pressure of lava piled would bring debris cascading. Figure 2: System output on excerpt from Figure 1.

Comparison with state-of-the-art An obvious evaluation experiment would involve comparing the ILP model without any discourse constraints against the discourse informed model presented in this work. Unfortunately, the two models obtain markedly different compression rates[6] which renders the comparison of their outputs problematic. To put the comparison on an equal footing, we evaluated our approach against a state-of-the-art model that achieves a compression rate similar to ours without taking discourse-level information into account. McDonald (2006) formalises sentence compression in a discriminative large-margin learning framework as a classification task: pairs of words from the source sentence are classified as being adjacent or not in the target compression. A large number of features are defined over words, parts of speech, phrase structure trees and dependencies. These are gathered over adjacent words in the compression and the words in-between which were dropped.

It is important to note that McDonald (2006) is not a straw-man system. It achieves highly competitive performance compared with Knight and Marcu's (2002) noisy channel and decision tree models. Due to its discriminative nature, the model is able to use a large feature set and to optimise compression accuracy directly. In other words, McDonald's model has a head start against our own model which does not utilise a parallel corpus and has only a few constraints. The comparison of the two systems allows us to investigate whether discourse information is redundant when using a powerful sentence compression model.

Corpus Previous work on sentence compression has used almost exclusively the Ziff-Davis, a compression corpus derived automatically from document-abstract pairs (Knight and Marcu 2002). Unfortunately, this corpus is not suitable for our purposes since it consists of isolated sentences. We thus created a document-based compression corpus manually. Following Clarke and Lapata (2006a), we asked annotators to produce compressions for 82 stories (1,629 sentences) from the BNC and the LA Times Washington Post.[7] 48 documents (962 sentences) were used for training, 3 for development (63 sentences), and 31 for testing (604 sentences).

Parameter Estimation Our parameters for the ILP model followed closely Clarke and Lapata (2006a). We used a language model trained on 25 million tokens from the North American News corpus. The significance score was based on 25 million tokens from the same corpus. Our re-implementation of McDonald (2006) used an identical feature set, and a slightly modified loss function to encourage compression on our data set.[8]

Evaluation Previous studies evaluate how well-formed the automatically derived compressions are out of context. The target sentences are typically rated by naive subjects on two dimensions, grammaticality and importance (Knight and Marcu 2002). Automatic evaluation measures have also been proposed. Riezler et al. (2003) compare the grammatical relations found in the system output against those found in a gold standard using F-score which Clarke and Lapata (2006b) show correlates reliably with human judgements.

Following previous work, sentence-based compressions were evaluated automatically using F-score computed over grammatical relations which we obtained by RASP (Briscoe and Carroll 2002). Besides individual sentences, our goal was to evaluate the compressed document as whole. Our evaluation methodology was motivated by two questions: (1) are the documents readable? and (2) how much key information is preserved between the source document and its target compression? We assume here that the compressed document is to function as a replacement for the original. We can thus measure the extent to which the compressed version can be

[6] The discourse agnostic ILP model has a compression rate of 81.2%; when discourse constraints are include the rate drops to 65.4%.

[7] The corpus is available from `http://homepages.inf.ed.ac.uk/s0460084/data/`.

[8] McDonald's (2006) results are reported on the Ziff-Davis corpus.

Figure 3: Example questions with answer key.

used to find answers for questions which are derived from the original and represent its core content.

We therefore employed a question-answering evaluation paradigm which has been previously used for summarisation evaluation and text comprehension (Mani et al. 2002; Morris et al. 1992). The overall objective of our Q&A task is to determine how accurate each document (generated by different compression systems) is at answering questions. For this we require a methodology for constructing Q&A pairs and for scoring each document.

Two annotators were independently instructed to create Q&A pairs for the original documents in the test set. Each annotator read the document and then drafted no more than ten questions and answers related to its content. Annotators were asked to create factual-based questions which required an unambiguous answer; these were typically who/what/where/when/how style questions. Annotators then compared and revised their question-answer pairs to create a common agreed upon set. Revisions typically involved merging questions, rewording and simplifying questions, and in some cases splitting a question into multiple questions. Documents for which too few questions were created or for which questions or answers were too ambiguous were removed. This left an evaluation set of six documents with between five to eight concise questions per document. Some example questions corresponding to the document from Figure 1 are given in Figure 3; correct answers are shown in parentheses.

Compressed documents and their accompanying questions were presented to human subjects who were asked to provide answers as best they could. We elicited answers for six documents in three compression conditions: gold standard, using the ILP discourse model, and McDonald's (2006) model. Each participant was also asked to rate the readability of the compressed document on a seven point scale. A Latin Square design prevented participants from seeing two different compressions of the same document.

Model	CompR	F-Score
McDonald	60.1%	36.0%*
Discourse ILP	65.4%	39.6%
Gold Standard	70.3%	—–

Table 1: Compression results: compression rate and relation-based F-score; * sig. diff. from Discourse ILP ($p < 0.05$ using the Student t test).

Model	Readability	Q&A
McDonald	2.6*	53.7%*†
Discourse ILP	3.0*	68.3%
Gold Standard	5.5†	80.7%

Table 2: Human Evaluation Results: average readability ratings and average percentage of questions answered correctly. *: sig. diff. from Gold Standard; †: sig. diff. from Discourse ILP.

The study was conducted remotely over the Internet. Participants were presented with a set of instructions that explained the Q&A task and provided examples. Subjects were first asked to read the compressed document and rate its readability. Questions were then presented one at a time and participants were allowed to consult the document for the answer. Once a participant had provided an answer they were not allowed to modify it. Thirty unpaid volunteers took part in our Q&A study. All were self reported native English speakers.

The answers provided by the participants were scored against the answer key. Answers were considered correct if they were identical to the answer key or subsumed by it. For instance, *Mount Etna* was considered a right answer to the first question from Figure 3. A compressed document receives a full score if subjects have answered all questions relating to it correctly.

6 Results

As a sanity check, we first assessed the compressions produced by our model and McDonald (2006) on a sentence-by-sentence basis without taking the documents into account. There is no hope for generating shorter documents if the compressed sentences are either too wordy or too ungrammatical. Table 1 shows the compression rates (CompR) for the two systems and evaluates the quality of their output using F-score based on grammatical relations. As can be seen, the Discourse ILP compressions are slightly longer than McDonald (65.4% vs. 60.1%) but closer to the human gold standard (70.3%). This is not surprising, the Discourse ILP model takes the entire document into account, and compression decisions will be slightly more conservative. The Discourse ILP's output is significantly better than McDonald in terms of F-score, indicating that discourse-level information is generally helpful. Both systems could use further improvement as inter-annotator agreement on this data yields an F-score of 65.8%.

Let us now consider the results of our document-based evaluation. Table 2 shows the mean readability ratings obtained for each system and the percentage of questions answered correctly. We used an Analysis of Variance (ANOVA) to examine the effect of compression type (McDonald, Discourse ILP, Gold Standard). The ANOVA revealed a reliable effect on both readability and Q&A. Post-hoc Tukey tests showed that McDonald and the Discourse ILP model do not differ significantly in terms of readability. However, they are significantly less readable than the gold standard ($\alpha < 0.05$). For the Q&A task we observe that our system is significantly better than McDonald ($\alpha < 0.05$) and not significantly worse than the gold standard.

These results indicate that the automatic systems lag behind the human gold standard in terms of readability. When reading entire documents, subjects are less tolerant of ungrammatical constructions. We also find out that despite relatively low readability, the documents are overall understandable. The discourse informed model generates more informative documents — the number of questions answered correctly increases by 15% in comparison to McDonald. This is an encouraging result suggesting that there may be advantages in developing compression models that exploit contextual information.

7 Conclusions and Future Work

In this paper we proposed a novel method for automatic sentence compression. Central in our approach is the use of discourse-level information which we argue is an important prerequisite for document (as opposed to sentence) compression. Our model uses integer programming for inferring globally optimal compressions in the presence of linguistically motivated constraints. Our discourse constraints aim to capture local coherence and are inspired by centering theory and lexical chains. We showed that our model can be successfully employed to produce compressed documents that preserve most of the original's core content.

Our approach to document compression differs from most summarisation work in that our summaries are fairly long. However, we believe this is the first step into understanding how compression can help summarisation. In the future, we will interface our compression model with sentence extraction. The discourse annotations can help guide the extraction method into selecting topically related sentences which can consequently be compressed together. The compression rate can be tailored through additional constraints which act on the output length to ensure precise word limits are obeyed.

We also plan to study the effect of global discourse structure (Daumé III and Marcu 2002) on the compression task. In general, we will assess the impact of discourse information more systematically by incorporating it into generative and discriminative modelling paradigms.

Abstract

Shallow semantic parsing, the automatic identification and labeling of sentential constituents, has recently received much attention. Our work examines whether semantic role information is beneficial to question answering. We introduce a general framework for answer extraction which exploits semantic role annotations in the FrameNet paradigm. We view semantic role assignment as an optimization problem in a bipartite graph and answer extraction as an instance of graph matching. Experimental results on the TREC datasets demonstrate improvements over state-of-the-art models.

1 Introduction

Recent years have witnessed significant progress in developing methods for the automatic identification and labeling of semantic roles conveyed by sentential constituents.[1] The success of these methods, often referred to collectively as *shallow semantic parsing* (Gildea and Jurafsky, 2002), is largely due to the availability of resources like FrameNet (Fillmore et al., 2003) and PropBank (Palmer et al., 2005), which document the surface realization of semantic roles in real world corpora.

More concretely, in the FrameNet paradigm, the meaning of predicates (usually verbs, nouns, or adjectives) is conveyed by *frames*, schematic representations of situations. Semantic roles (or *frame elements*) are defined for each frame and correspond to salient entities present in the evoked situation. Predicates with similar semantics instantiate the same frame and are attested with the same roles. The FrameNet database lists the surface syntactic realizations of semantic roles, and provides annotated example sentences from the British National Corpus. For example, the frame *Commerce_Sell* has three core semantic roles, namely *Buyer*, *Goods*, and *Seller* — each expressed by an indirect object, a direct object, and a subject (see sentences (1a)–(1c)). It can also be attested with non-core (peripheral) roles (e.g., *Means, Manner*, see (1d) and (1e)) that are more generic and can be instantiated in several frames, besides *Commerce_Sell*. The verbs *sell*, *vend*, and *retail* can evoke this frame, but also the nouns *sale* and *vendor*.

(1)
a. [Lee]$_{Seller}$ sold a textbook [to Abby]$_{Buyer}$.
b. [Kim]$_{Seller}$ sold [the sweater]$_{Goods}$.
c. [My company]$_{Seller}$ has sold [more than three million copies]$_{Goods}$.
d. [Abby]$_{Seller}$ sold [the car]$_{Goods}$ [for cash]$_{Means}$.
e. [He]$_{Seller}$ [reluctanctly]$_{Manner}$ sold [his rock]$_{Goods}$.

By abstracting over surface syntactic configurations, semantic roles offer an important first step towards deeper text understanding and hold promise for a range of applications requiring broad coverage semantic processing. Question answering (QA) is often cited as an obvious beneficiary of semantic

[1] The approaches are too numerous to list; we refer the interested reader to Carreras and Màrquez (2005) for an overview.

Proceedings of the 2007 Joint Conference on Empirical Methods in Natural Language Processing and Computational Natural Language Learning, pp. 12–21, Prague, June 2007. ©2007 Association for Computational Linguistics

role labeling (Gildea and Jurafsky, 2002; Palmer et al., 2005; Narayanan and Harabagiu, 2004). Faced with the question *Q: What year did the U.S. buy Alaska?* and the retrieved sentence *S: . . . before Russia sold Alaska to the United States in 1867*, a hypothetical QA system must identify that *United States* is the *Buyer* despite the fact that it is attested in one instance as a subject and in another as an object. Once this information is known, isolating the correct answer (i.e., *1867*) can be relatively straightforward.

Although conventional wisdom has it that semantic role labeling ought to improve answer extraction, surprising little work has been done to this effect (see Section 2 for details) and initial results have been mostly inconclusive or negative (Sun et al., 2005; Kaisser, 2006). There are at least two good reasons for these findings. First, shallow semantic parsers trained on declarative sentences will typically have poor performance on questions and generally on out-of-domain data. Second, existing resources do not have exhaustive coverage and recall will be compromised, especially if the question answering system is expected to retrieve answers from unrestricted text. Since FrameNet is still under development, its coverage tends to be more of a problem in comparison to other semantic role resources such as PropBank.

In this paper we propose an answer extraction model which effectively incorporates FrameNet-style semantic role information. We present an automatic method for semantic role assignment which is conceptually simple and does not require extensive feature engineering. A key feature of our approach is the comparison of dependency relation paths attested in the FrameNet annotations and raw text. We formalize the search for an optimal role assignment as an optimization problem in a bipartite graph. This formalization allows us to find an exact, globally optimal solution. The graph-theoretic framework goes some way towards addressing coverage problems related with FrameNet and allows us to formulate answer extraction as a graph matching problem. As a byproduct of our main investigation we also examine the issue of FrameNet coverage and show how much it impacts performance in a TREC-style question answering setting.

In the following section we provide an overview of existing work on question answering systems that exploit semantic role-based lexical resources. Then we define our learning task and introduce our approach to semantic role assignment and answer extraction in the context of QA. Next, we present our experimental framework and data. We conclude the paper by presenting and discussing our results.

2 Related Work

Question answering systems have traditionally depended on a variety of lexical resources to bridge surface differences between questions and potential answers. WordNet (Fellbaum, 1998) is perhaps the most popular resource and has been employed in a variety of QA-related tasks ranging from query expansion, to axiom-based reasoning (Moldovan et al., 2003), passage scoring (Paranjpe et al., 2003), and answer filtering (Leidner et al., 2004). Besides WordNet, recent QA systems increasingly rely on syntactic information as a means of abstracting over word order differences and structural alternations (e.g., passive vs. active voice). Most syntax-based QA systems (Wu et al., 2005) incorporate some means of comparison between the tree representing the question with the subtree surrounding the answer candidate. The assumption here is that appropriate answers are more likely to have syntactic relations in common with their corresponding question. Syntactic structure matching has been applied to passage retrieval (Cui et al., 2005) and answer extraction (Shen and Klakow, 2006).

Narayanan and Harabagiu (2004) were the first to stress the importance of semantic roles in answering complex questions. Their system identifies predicate argument structures by merging semantic role information from PropBank and FrameNet. Expected answers are extracted by performing probabilistic inference over the predicate argument structures in conjunction with a domain specific topic model. Sun et al. (2005) incorporate semantic analysis in their TREC05 QA system. They use ASSERT (Pradhan et al., 2004), a publicly available shallow semantic parser trained on PropBank, to generate predicate-argument structures which subsequently form the basis of comparison between question and answer sentences. They find that semantic analysis does not boost performance due to the low recall of the semantic parser. Kaisser (2006) proposes a

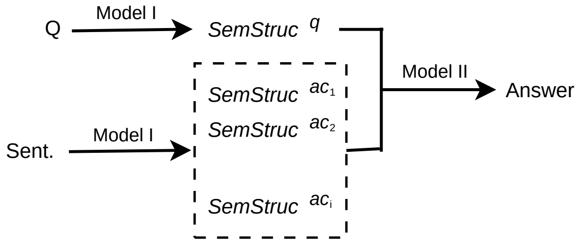

Figure 1: Architecture of answer extraction

question paraphrasing method based on FrameNet. Questions are assigned semantic roles by matching their dependency relations with those attested in the FrameNet annotations. The assignments are used to create question reformulations which are submitted to Google for answer extraction. The semantic role assignment module is not probabilistic, it relies on strict matching, and runs into severe coverage problems.

In line with previous work, our method exploits syntactic information in the form of dependency relation paths together with FrameNet-like semantic roles to smooth lexical and syntactic divergences between question and answer sentences. Our approach is less domain dependent and resource intensive than Narayanan and Harabagiu (2004), it solely employs a dependency parser and the FrameNet database. In contrast to Kaisser (2006), we model the semantic role assignment and answer extraction tasks numerically, thereby alleviating the coverage problems encountered previously.

3 Problem Formulation

We briefly summarize the architecture of the QA system we are working with before formalizing the mechanics of our FrameNet-based answer extraction module. In common with previous work, our overall approach consists of three stages: (a) determining the expected answer type of the question, (b) retrieving passages likely to contain answers to the question, and (c) performing a match between the question words and retrieved passages in order to extract the answer. In this paper we focus on the last stage: question and answer sentences are normalized to a FrameNet-style representation and answers are retrieved by selecting the candidate whose semantic structure is most similar to the question.

The architecture of our answer extraction module is shown in Figure 1. Semantic structures for questions and sentences are automatically derived using the model described in Section 4 (Model I). A semantic structure $SemStruc = \langle p, Set(SRA) \rangle$ consists of a predicate p and a set of semantic role assignments $Set(SRA)$. p is a word or phrase evoking a frame F of FrameNet. A semantic role assignment SRA is a ternary structure $\langle w, SR, s \rangle$, consisting of frame element w, its semantic role SR, and score s indicating to what degree SR qualifies as a label for w.

For a question q, we generate a semantic structure $SemStruc^q$. Question words, such as *what*, *who*, *when*, etc., are considered expected answer phrases (*EAP*s). We require that *EAP*s are frame elements of $SemStruc^q$. Likely answer candidates are extracted from answer sentences following some preprocessing steps detailed in Section 6. For each candidate ac, we derive its semantic structure $SemStruc^{ac}$ and assume that ac is a frame element of $SemStruc^{ac}$. Question and answer semantic structures are compared using a model based on graph matching detailed in Section 5 (Model II). We calculate the similarity of all derived pairs $\langle SemStruc^q, SemStruc^{ac} \rangle$ and select the candidate with the highest value as an answer for the question.

4 Semantic Structure Generation

Our method crucially exploits the annotated sentences in the FrameNet database together with the output of a dependency parser. Our guiding assumption is that sentences that share dependency relations will also share semantic roles as long as they evoke the same or related frames. This is motivated by much research in lexical semantics (e.g., Levin (1993)) hypothesizing that the behavior of words, particularly with respect to the expression and interpretation of their arguments, is to a large extent determined by their meaning. We first describe how predicates are identified and then introduce our model for semantic role labeling.

Predicate Identification Predicate candidates are identified using a simple look-up procedure which compares POS-tagged tokens against FrameNet entries. For efficiency reasons, we make the simplifying assumption that questions have only one predicate which we select heuristically: (1) verbs are preferred to other parts of speech, (2) if there is more than one verb in the question, preference is given to the verb with the highest level of embedding in the dependency tree, (3) if no verbs are present, a noun is chosen. For example, in *Q: Who beat Floyd Patterson to take the title away?*, *beat*, *take away*, and *title* are identified as predicate candidates and *beat* is selected the main predicate of the question. For answer sentences, we require that the predicate is either identical or semantically related to the question predicate (see Section 5).

In the example given above, the predicate *beat* evoques a single frame (i.e., *Cause_harm*). However, predicates often have multiple meanings thus evoquing more than one frame. Knowing which is the appropriate frame for a given predicate impacts the semantic role assignment task; selecting the wrong frame will unavoidably result in erroneous semantic roles. Rather than disambiguiting polysemous predicates prior to semantic role assignment, we perform the assignment for each frame evoqued by the predicate.

Semantic Role Assignment Before describing our approach to semantic role labeling we define dependency relation paths. A relation path R is a relation sequence $\langle r_1, r_2, ..., r_L \rangle$, in which r_l ($l = 1, 2, ..., L$) is one of predefined dependency relations with suffix of traverse direction. An example of a relation path is $R = \langle subj_U, obj_D \rangle$, where the subscripts U and D indicate upward and downward movement in trees, respectively. Given an unannotated sentence whose roles we wish to label, we assume that words or phrases w with a dependency path connecting them to p are frame elements. Each frame element is represented by an *unlabeled* dependency path R_w which we extract by traversing the dependency tree from w to p. Analogously, we extract from the FrameNet annotations all dependency paths R_{SR} that are *labeled* with semantic role information and correspond to p. We next measure the compatibility of labeled and unlabeled paths as follows:

(2) $$s(w, SR) = \max_{R_{SR} \in M} [sim(R_w, R_{SR}) \cdot P(R_{SR})]$$

where M is the set of dependency relation paths for SR in FrameNet, $sim(R_w, R_{SR})$ the similarity between paths R_w and R_{SR} weighted by the relative frequency of R_{SR} in FrameNet ($P(R_{SR})$). We consider both core and non-core semantic roles instantiated by frames with at least one annotation in FrameNet. Core roles tend to have more annotations in Framenet and consequently are considered more probable.

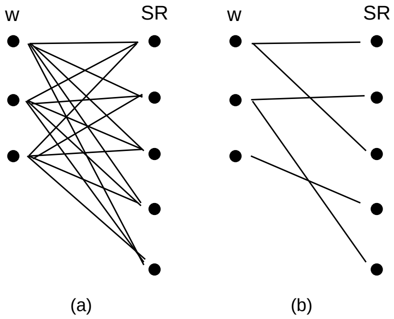

Figure 2: Sample original bipartite graph (a) and its subgraph with edge covers (b). In each graph, the left partition represents frame elements and the right partition semantic roles.

We measure $sim(R_w, R_{SR})$, by adapting a string kernel to our task. Our hypothesis is that the more common substrings two dependency paths have, the more similar they are. The string kernel we used is similar to Leslie (2002) and defined as the sum of weighted common dependency relation subsequences between R_w and R_{SR}. For efficiency, we consider only unigram and bigram subsequences. Subsequences are weighted by a metric akin to $tf \cdot idf$ which measures the degree of association between a candidate SR and the dependency relation r present in the subsequence:

(3) $$weight_{SR}(r) = f_r \cdot \log\left(1 + \frac{N}{n_r}\right)$$

where f_r is the frequency of r occurring in SR; N is the total number of SRs evoked by a given frame; and n_r is the number of SRs containing r.

For each frame element we thus generate a set of semantic role assignments $Set(SRA)$. This initial assignment can be usefully represented as a complete bipartite graph in which each frame element (word or phrase) is connected to the semantic roles licensed by the predicate and vice versa. (see Figure 2a). Edges are weighted and represent how compatible the frame elements and semantic roles are (see equation (2)). Now, for each frame element w

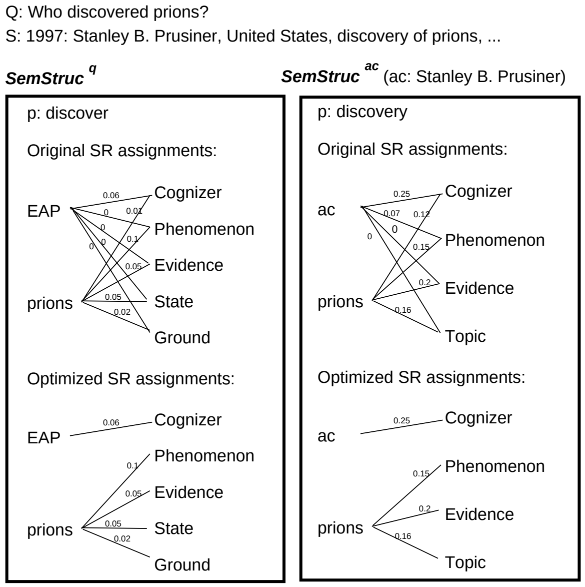

Figure 3: Semantic structures induced by our model for a question and answer sentence

we could simply select the semantic role with the highest score. However, this decision procedure is *local*, i.e., it yields a semantic role assignment for each frame element independently of all other elements. We therefore may end up with the same role being assigned to two frame elements or with frame elements having no role at all. We remedy this shortcoming by treating the semantic role assignment as a *global* optimization problem.

Specifically, we model the interaction between *all* pairwise labeling decisions as a *minimum weight bipartite edge cover problem* (Eiter and Mannila, 1997; Cormen et al., 1990). An edge cover is a subgraph of a bipartite graph so that each node is linked to at least one node of the other partition. This yields a semantic role assignment for all frame elements (see Figure 2b where frame elements and roles are adjacent to an edge). Edge covers have been successfully applied in several natural language processing tasks, including machine translation (Taskar et al., 2005) and annotation projection (Padó and Lapata, 2006).

Formally, optimal edge cover assignments are solutions of following optimization problem:

(4)
$$\max_{E \text{ is edge cover}} \prod_{(nd^w, nd^{SR}) \in E} s(nd^w, nd^{SR})$$

where, $s(nd^w, nd^{SR})$ is the compatibility score between the frame element node nd^w and semantic role node nd^{SR}. Edge covers can be computed efficiently in cubic time using algorithms for the equivalent linear assignment problem. Our experiments used Jonker and Volgenant's (1987) solver.[2]

Figure 3 shows the semantic role assignments generated by our model for the question *Q: Who discovered prions?* and the candidate answer sentence *S: 1997: Stanley B. Prusiner, United States, discovery of prions...* Here we identify two predicates, namely *discover* and *discovery*. The expected answer phrase (EAP) *who* and the answer candidate *Stanley B. Prusiner* are assigned the COGNIZER role. Note that frame elements can bear multiple semantic roles. By inducing a soft labeling we hope to render the matching of questions and answers more robust, thereby addressing to some extent the coverage problems associated with FrameNet.

5 Semantic Structure Matching

We measure the similarity between a question and its candidate answer by matching their predicates and semantic role assignments. Since SRs are frame-specific, we prioritize frame matching to SR matching. Two predicates match if they evoke the same frame or one of its hypernyms (or hyponyms). The latter are expressed by the *Inherits From* and *Is Inherited By* relations in the frame definitions. If the predicates match, we examine whether the assigned semantic roles match. Since we represent SR assignments as graphs with edge covers, we can also formalize SR matching as a graph matching problem.

The similarity between two graphs is measured as the sum of similarities between their subgraphs. We first decompose a graph into subgraphs consisting of one frame element node w and a set of SR nodes connected to it. The similarity between two subgraphs $SubG_1$, and $SubG_2$ is then formalized as:

(5)
$$Sim(SubG_1, SubG_2) = \sum_{\substack{nd_1^{SR} \in SubG_1 \\ nd_2^{SR} \in SubG_2 \\ nd_1^{SR} = nd_2^{SR}}} \frac{1}{|s(nd^w, nd_1^{SR}) - s(nd^w, nd_2^{SR})| + 1}$$

where, nd_1^{SR} and nd_2^{SR} are semantic role nodes connected to a frame element node nd^w in $SubG_1$ and

[2] The software is available from `http://www.magiclogic.com/assignment.html` .

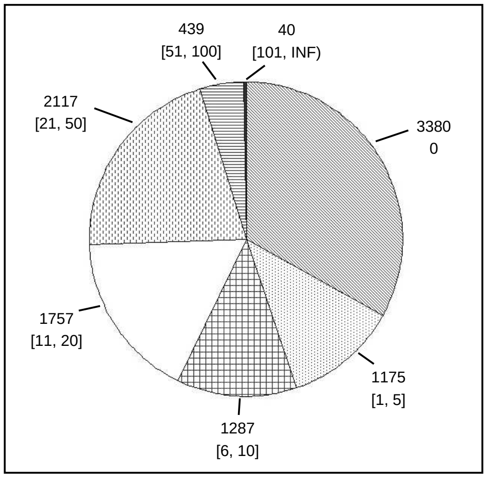

Figure 4: Distribution of Numbers of Predicates and annotated sentences; each sub-pie, lists the number of predicates (above) with their corresponding range of annotated sentences (below)

$SubG_2$, respectively. $s(nd^w, nd_1^{sr})$ and $s(nd^w, nd_2^{SR})$ are edge weights between two nodes in corresponding subgraphs (see (2)). Our intuition here is that the more semantic roles two subgraphs share for a given frame element, the more similar they are and the closer their corresponding edge weights should be. Edge weights are normalized by dividing by the sum of all edges in a subgraph.

6 Experimental Setup

Data All our experiments were performed on the TREC02–05 factoid questions. We excluded NIL questions since TREC doesn't supply an answer for them. We used the FrameNet V1.3 lexical database. It contains 10,195 predicates grouped into 795 semantic frames and 141,238 annotated sentences. Figure 4 shows the number of annotated sentences available for different predicates. As can be seen, there are 3,380 predicates with no annotated sentences and 1,175 predicates with less than 5 annotated sentences. All FrameNet sentences, questions, and answer sentences were parsed using MiniPar (Lin, 1994), a robust dependency parser.

As mentioned in Section 4 we extract dependency relation paths by traversing the dependency tree from the frame element node to the predicate node. We used all dependency relations provided by MiniPar (42 in total). In order to increase coverage, we combine all relation paths for predicates that evoke the same frame and are labeled with the same POS tag. For example, *found* and *establish* are both instances of the frame *Intentionally_create* but the database does not have any annotated sentences for *found.v*. In default of not assigning any role labels for *found.v*, our model employs the relation paths for the semantically related *establish.v*.

Preprocessing Here we summarize the steps of our QA system preceding the assignment of semantic structure and answer extraction. For each question, we recognize its expected answer type (e.g., in *Q: Which record company is Fred Durst with?* we would expect the answer to be an *ORGANIZATION*). Answer types are determined using classification rules similar to Li and Roth (2002). We also reformulate questions into declarative sentences following the strategy proposed in Brill et al. (2002).

The reformulated sentences are submitted as queries to an IR engine for retrieving sentences with relevant answers. Specifically, we use the Lemur Toolkit[3], a state-of-the-art language model-driven search engine. We work only with the 50 top-ranked sentences as this setting performed best in previous experiments of our QA system. We also add to Lemur's output gold standard sentences, which contain and support an answer for each question. Specifically, documents relevant for each question are retrieved from the AQUAINT Corpus[4] according to TREC supplied judgments. Next, sentences which match both the TREC provided answer pattern and at least one question key word are extracted and their suitability is manually judged by humans. The set of relevant sentences thus includes at least one sentence with an appropriate answer as well as sentences that do not contain any answer specific information. This setup is somewhat idealized, however it allows us to evaluate in more detail our answer extraction module (since when an answer is not found, we know it is the fault of our system).

Relevant sentences are annotated with their named entities using Lingpipe[5], a MUC-based named entity recognizer. When we successfully classify a question with an expected answer type

[3] See http://www.lemurproject.org/ for details.

[4] This corpus consists of English newswire texts and is used as the main document collection in official TREC evaluations.

[5] The software is available from www.alias-i.com/lingpipe/

(e.g., *ORGANIZATION* in the example above), we assume that all NPs attested in the set of relevant sentences with the same answer type are candidate answers; in cases where no answer type is found (e.g., as in *Q: What are prions made of?*), all NPs in the relevant answers set are considered candidate answers.

Baseline We compared our answer extraction method to a QA system that exploits solely syntactic information without making use of FrameNet or any other type of role semantic annotations. For each question, the baseline identifies key phrases deemed important for answer identification. These are verbs, noun phrases, and expected answer phrases (EAPs, see Section 3). All dependency relation paths connecting a key phrase and an EAP are compared to those connecting the same key phrases and an answer candidate. The similarity of question and answer paths is computed using a simplified version of the similarity measure[6] proposed in Shen and Klakow (2006).

Our second baseline employs Shalmaneser (Erk and Padó, 2006), a publicly available shallow semantic parser[7], for the role labeling task instead of the graph-based model presented in Section 4. The software is trained on the FrameNet annotated sentences using a standard feature set (see Carreras and Màrquez (2005) for details). We use Shalmaneser to parse questions and answer sentences. The parser makes hard decisions about the presence or absence of a semantic role. Unfortunately, this prevents us from using our method for semantic structure matching (see Section 5) which assumes a soft labeling. We therefore came up with a simple matching strategy suitable for the parser's output. For question and answer sentences matching in their frame assignment, phrases bearing the same semantic role as the EAP are considered answer candidates. The latter are ranked according to word overlap (i.e., identical phrases are ranked higher than phrases with no overlap at all).

7 Results

Our evaluation was motivated by the following questions: (1) How does the incompleteness of FrameNet impact QA performance on the TREC data sets? In particular, we wanted to examine whether there are questions for which in principle no answer can be found due to missing frame entries or missing annotated sentences. (2) Are all questions and their corresponding answers amenable to a FrameNet-style analysis? In other words, we wanted to assess whether questions and answers often evoke the same or related frames (with similar roles). This is a prerequisite for semantic structure matching and ultimately answer extraction. (3) Do the graph-based models introduced in this paper bring any performance gains over state-of-the-art shallow semantic parsers or more conventional syntax-based QA systems? Recall that our graph-based models were designed especially for the QA answer extraction task.

Our results are summarized in Tables 1–3. Table 1 records the number of questions to be answered for the TREC02–05 datasets (Total). We also give information regarding the number of questions which are in principle *unanswerable* with a FrameNet-style semantic role analysis.

Column NoFrame shows the number of questions which don't have an appropriate frame or predicate in the database. For example, there is currently no predicate entry for *sponsor* or *sink* (e.g., *Q: Who is the sponsor of the International Criminal Court?* and *Q: What date did the Lusitania sink?*). Column NoAnnot refers to questions for which no semantic role labeling is possible because annotated sentences for the relevant predicates are missing. For instance, there are no annotations for *win* (e.g., *Q: What division did Floyd Patterson win?*) or for *hit* (e.g., *Q: What was the Beatles' first number one hit?*). This problem is not specific to our method which admittedly relies on FrameNet annotations for performing the semantic role assignment (see Section 4). Shallow semantic parsers trained on FrameNet would also have trouble assigning roles to predicates for which no data is available.

Finally, column NoMatch reports the number of questions which cannot be answered due to frame

[6] Shen and Klakow (2006) use a dynamic time warping algorithm to calculate the degree to which dependency relation paths are correlated. Correlations for individual relations are estimated from training data whereas we assume a binary value (1 for identical relations and 0 otherwise). The modification was necessary to render the baseline system comparable to our answer extraction model which is unsupervised.

[7] The software is available from http://www.coli.uni-saarland.de/projects/salsa/shal/ .

Data	Total	NoFrame		NoAnnot		NoMatch		Rest	
TREC02	444	87	(19.6)	29	(6.5)	176	(39.6)	152	(34.2)
TREC03	380	55	(14.5)	30	(7.9)	183	(48.2)	112	(29.5)
TREC04	203	47	(23.1)	14	(6.9)	67	(33.0)	75	(36.9)
TREC05	352	70	(19.9)	23	(6.5)	145	(41.2)	114	(32.4)

Table 1: Number of questions which cannot be answered using a FrameNet style semantic analysis; numbers in parentheses are percentages of Total (NoFrame: frames or predicates are missing; NoAnnot: annotated sentences are missing, NoMatch: questions and candidate answers evoke different frames.

mismatches. Consider *Q: What does AARP stand for?* whose answer is found in *S: The American Association of Retired Persons (AARP) qualify for discounts…*. The answer and the question evoke different frames; in fact here a semantic role analysis is not relevant for locating the right answer. As can be seen NoMatch cases are by far the most frequent. The number of questions remaining after excluding NoFrame, NoAnnot, and NoMatch are shown under the Rest heading in Table 1.

These results indicate that FrameNet-based semantic role analysis applies to approximately 35% of the TREC data. This means that an extraction module relying solely on FrameNet will have poor performance, since it will be unable to find answers for more than half of the questions beeing asked. We nevertheless examine whether our model brings any performance improvements on this limited dataset which is admittedly favorable towards a FrameNet style analysis. Table 2 shows the results of our answer extraction module (SemMatch) together with two baseline systems. The first baseline uses only dependency relation path information (SynMatch), whereas the second baseline (SemParse) uses Shalmaneser, a state-of-the-art shallow semantic parser for the role labeling task. We consider an answer correct if it is returned with rank 1. As can be seen, SemMatch is significantly better than both SynMatch and SemParse, whereas the latter is significantly worse than SynMatch.

Model	TREC02	TREC03	TREC04	TREC05
SemParse	13.16	8.92	17.33	13.16
SynMatch	35.53*	33.04*	40.00*	36.84*
SemMatch	53.29*†	49.11*†	54.67*†	59.65*†

Table 2: System Performance on subset of TREC datasets (see Rest column in Table 1); *: significantly better than SemParse; †: significantly better than SynMatch ($p < 0.01$, using a χ^2 test).

Model	TREC02	TREC03	TREC04	TREC05
SynMatch	32.88*	30.70*	35.95*	34.38*
+SemParse	25.23	23.68	28.57	26.70
+SemMatch	38.96*†	35.53*†	42.36*†	41.76*†

Table 3: System Performance on TREC datasets (see Total column in Table 1); *: significantly better than +SemParse; †: significantly better than SynMatch ($p < 0.01$, using a χ^2 test).

Although promising, the results in Table 2 are not very informative, since they show performance gains on partial data. Instead of using our answer extraction model on its own, we next combined it with the syntax-based system mentioned above (SynMatch, see also Section 6 for details). If FrameNet is indeed helpful for QA, we would expect an ensemble system to yield better performance over a purely syntactic answer extraction module. The two systems were combined as follows. Given a question, we first pass it to our FrameNet model; if an answer is found, our job is done; if no answer is returned, the question is passed on to SynMatch. Our results are given in Table 3. +SemMatch and +SemParse are ensemble systems using SynMatch together with the QA specific role labeling method proposed in this paper and Shalmaneser, respectively. We also compare these systems against SynMatch on its own.

We can now attempt to answer our third question concerning our model's performance on the TREC data. Our experiments show that a FrameNet-enhanced answer extraction module significantly outperforms a similar module that uses only syntactic information (compare SynMatch and +SemMatch in Table 3). Another interesting finding is that the shallow semantic parser performs considerably worse in comparison to our graph-based models and the syntax-based system. Inspection of the parser's output highlights two explanations for this. First, the shallow semantic parser has difficulty assigning accurate semantic roles to questions (even when they are reformulated as declarative sentences). And secondly, it tends to favor precision over recall, thus reducing the number of questions for which answers can be found. A similar finding is reported in Sun et al. (2005) for a PropBank trained parser.

8 Conclusion

In this paper we assess the contribution of semantic role labeling to open-domain factoid question answering. We present a graph-based answer extraction model which effectively incorporates FrameNet style role semantic information and show that it achieves promising results. Our experiments show that the proposed model can be effectively combined with a syntax-based system to obtain performance superior to the latter when used on its own. Furthermore, we demonstrate performance gains over a shallow semantic parser trained on the FrameNet annotated corpus. We argue that performance gains are due to the adopted graph-theoretic framework which is robust to coverage and recall problems.

We also provide a detailed analysis of the appropriateness of FrameNet for QA. We show that performance can be compromised due to incomplete coverage (i.e., missing frame or predicate entries as well as annotated sentences) but also because of mismatching question-answer representations. The question and the answer may evoke different frames or the answer simply falls outside the scope of a given frame (i.e., in a non predicate-argument structure). Our study shows that mismatches are relatively frequent and motivates the use of semantically informed methods in conjunction with syntax-based methods.

Important future directions lie in evaluating the contribution of alternative semantic role frameworks (e.g., PropBank) to the answer extraction task and developing models that learn semantic roles directly from unannotated text without the support of FrameNet annotations (Grenager and Manning, 2006). Beyond question answering, we also plan to investigate the potential of our model for shallow semantic parsing since our experience so far has shown that it achieves good recall.

Acknowledgements We are grateful to Sebastian Padó for running Shalmaneser on our data. Thanks to Frank Keller and Amit Dubey for insightful comments and suggestions. The authors acknowledge the support of DFG (Shen; PhD studentship within the International Postgraduate College "Language Technology and Cognitive Systems") and EPSRC (Lapata; grant EP/C538447/1).

Abstract

This paper presents a syntax-driven approach to question answering, specifically the answer-sentence selection problem for short-answer questions. Rather than using syntactic features to augment existing statistical classifiers (as in previous work), we build on the idea that questions and their (correct) answers relate to each other via loose but predictable syntactic transformations. We propose a probabilistic quasi-synchronous grammar, inspired by one proposed for machine translation (D. Smith and Eisner, 2006), and parameterized by mixtures of a robust nonlexical syntax/alignment model with a(n optional) lexical-semantics-driven log-linear model. Our model learns soft alignments as a hidden variable in discriminative training. Experimental results using the TREC dataset are shown to significantly outperform strong state-of-the-art baselines.

1 Introduction and Motivation

Open-domain question answering (QA) is a widely-studied and fast-growing research problem. State-of-the-art QA systems are extremely complex. They usually take the form of a pipeline architecture, chaining together modules that perform tasks such as answer type analysis (identifying whether the correct answer will be a person, location, date, etc.), document retrieval, answer candidate extraction, and answer reranking. This architecture is so predominant that each task listed above has evolved into its own sub-field and is often studied and evaluated independently (Shima et al., 2006).

At a high level, the QA task boils down to only two essential steps (Echihabi and Marcu, 2003). The first step, **retrieval**, narrows down the search space from a corpus of millions of documents to a focused set of maybe a few hundred using an IR engine, where efficiency and recall are the main focus. The second step, **selection**, assesses each candidate answer string proposed by the first step, and finds the one that is most likely to be an answer to the given question. The granularity of the target answer string varies depending on the type of the question. For example, answers to factoid questions (e.g., Who, When, Where) are usually single words or short phrases, while definitional questions and other more complex question types (e.g., How, Why) look for sentences or short passages. In this work, we fix the granularity of an answer to a single sentence.

Earlier work on answer selection relies only on the surface-level text information. Two approaches are most common: surface pattern matching, and similarity measures on the question and answer, represented as bags of words. In the former, patterns for a certain answer type are either crafted manually (Soubbotin and Soubbotin, 2001) or acquired from training examples automatically (Ittycheriah et al., 2001; Ravichandran et al., 2003; Licuanan and Weischedel, 2003). In the latter, measures like cosine-similarity are applied to (usually) bag-of-words representations of the question and answer. Although many of these systems have achieved very good results in TREC-style evaluations, shallow methods using the bag-of-word representation clearly have their limitations. Examples of

Proceedings of the 2007 Joint Conference on Empirical Methods in Natural Language Processing and Computational Natural Language Learning, pp. 22–32, Prague, June 2007.

cases where the bag-of-words approach fails abound in QA literature; here we borrow an example used by Echihabi and Marcu (2003). The question is "*Who is the leader of France?*", and the sentence "Henri Hadjenberg, *who is the leader of France* 's Jewish community, endorsed ..." (note tokenization), which is not the correct answer, matches all keywords in the question in exactly the same order. (The correct answer is found in "Bush later met with French President Jacques Chirac.")

This example illustrates two types of variation that need to be recognized in order to connect this question-answer pair. The first variation is the change of the word "leader" to its semantically related term "president". The second variation is the syntactic shift from "leader of France" to "French president." It is also important to recognize that "France" in the first sentence is modifying "community", and therefore "Henri Hadjenberg" is the "leader of ... community" rather than the "leader of France." These syntactic and semantic variations occur in almost every question-answer pair, and typically they cannot be easily captured using shallow representations. It is also worth noting that such syntactic and semantic variations are not unique to QA; they can be found in many other closely related NLP tasks, motivating extensive community efforts in syntactic and semantic processing.

Indeed, in this work, we imagine a generative story for QA in which the question is generated from the answer sentence through a series of syntactic and semantic transformations. The same story has been told for **machine translation** (Yamada and Knight, 2001, *inter alia*), in which a target language sentence (the desired output) has undergone semantic transformation (word to word translation) and syntactic transformation (syntax divergence across languages) to generate the source language sentence (noisy-channel model). Similar stories can also be found in **paraphrasing** (Quirk et al., 2004; Wu, 2005) and **textual entailment** (Harabagiu and Hickl, 2006; Wu, 2005).

Our story makes use of a weighted formalism known as **quasi-synchronous grammar** (hereafter, QG), originally developed by D. Smith and Eisner (2006) for machine translation. Unlike most synchronous formalisms, QG does not posit a strict isomorphism between the two trees, and it provides an elegant description for the set of local configurations. In Section 2 we situate our contribution in the context of earlier work, and we give a brief discussion of quasi-synchronous grammars in Section 3. Our version of QG, called the **Jeopardy model**, and our parameter estimation method are described in Section 4. Experimental results comparing our approach to two state-of-the-art baselines are presented in Section 5. We discuss portability to cross-lingual QA and other applied semantic processing tasks in Section 6.

2 Related Work

To model the syntactic transformation process, researchers in these fields—especially in machine translation—have developed powerful grammatical formalisms and statistical models for representing and learning these tree-to-tree relations (Wu and Wong, 1998; Eisner, 2003; Gildea, 2003; Melamed, 2004; Ding and Palmer, 2005; Quirk et al., 2005; Galley et al., 2006; Smith and Eisner, 2006, *inter alia*). We can also observe a trend in recent work in textual entailment that more emphasis is put on explicit learning of the syntactic graph mapping between the entailed and entailed-by sentences (MacCartney et al., 2006).

However, relatively fewer attempts have been made in the QA community. As pointed out by Katz and Lin (2003), most early experiments in QA that tried to bring in syntactic or semantic features showed little or no improvement, and it was often the case that performance actually degraded (Litkowski, 1999; Attardi et al., 2001). More recent attempts have tried to augment the bag-of-words representation—which, after all, is simply a real-valued feature vector—with syntactic features. The usual similarity measures can then be used on the new feature representation. For example, Punyakanok et al. (2004) used approximate tree matching and tree-edit-distance to compute a similarity score between the question and answer parse trees. Similarly, Shen et al. (2005) experimented with dependency tree kernels to compute similarity between parse trees. Cui et al. (2005) measured sentence similarity based on similarity measures between dependency paths among aligned words. They used heuristic functions similar to mutual information to assign scores to matched pairs of dependency links. Shen and Klakow (2006) extend the idea further through the use of log-linear models to learn a scoring function for relation pairs.

Echihabi and Marcu (2003) presented a noisy-channel approach in which they adapted the IBM model 4 from statistical machine translation (Brown et al., 1990; Brown et al., 1993) and applied it to QA. Similarly, Murdock and Croft (2005) adopted a simple translation model from IBM model 1 (Brown et al., 1990; Brown et al., 1993) and applied it to QA. Porting the translation model to QA is not straightforward; it involves parse-tree pruning heuristics (the first two deterministic steps in Echihabi and Marcu, 2003) and also replacing the lexical translation table with a monolingual "dictionary" which simply encodes the identity relation. This brings us to the question that drives this work: is there a statistical translation-like model that is natural and accurate for question answering? We propose Smith and Eisner's (2006) quasi-synchronous grammar (Section 3) as a general solution and the Jeopardy model (Section 4) as a specific instance.

3 Quasi-Synchronous Grammar

For a formal description of QG, we recommend Smith and Eisner (2006). We briefly review the central idea here. QG arose out of the empirical observation that translated sentences often have *some* isomorphic syntactic structure, but not usually in entirety, and the strictness of the isomorphism may vary across words or syntactic rules. The idea is that, rather than a synchronous structure over the source and target sentences, a tree over the target sentence is modeled by a source-sentence-specific grammar that is inspired by the source sentence's tree.[1] This is implemented by a "sense"—really just a subset of nodes in the *source* tree—attached to each grammar node in the *target* tree. The senses define an alignment between the trees. Because it only loosely links the two sentences' syntactic structure, QG is particularly well-suited for QA insofar as QA is like "free" translation.

A concrete example that is easy to understand is a binary quasi-synchronous context-free grammar (denoted QCFG). Let V_S be the set of constituent tokens in the source tree. QCFG rules would take the augmented form

$$\begin{array}{rcl} \langle X, \mathbb{S}_1 \rangle & \rightarrow & \langle Y, \mathbb{S}_2 \rangle \langle Z, \mathbb{S}_3 \rangle \\ \langle X, \mathbb{S}_1 \rangle & \rightarrow & w \end{array}$$

where X, Y, and Z are ordinary CFG nonterminals, each $\mathbb{S}_i \in 2^{V_S}$ (subsets of nodes in the source tree to which the nonterminals align), and w is a target-language word. QG can be made more or less "liberal" by constraining the cardinality of the $\mathbb{S}_i$ (we force all $|\mathbb{S}_i| = 1$), and by constraining the relationships *among* the $\mathbb{S}_i$ mentioned in a single rule. These are called permissible "configurations." An example of a strict configuration is that a target parent-child pair must align (respectively) to a *source* parent-child pair. Configurations are shown in Table 1.

Here, following Smith and Eisner (2006), we use a weighted, quasi-synchronous *dependency* grammar. Apart from the obvious difference in application task, there are a few important differences with their model. First, we are not interested in the alignments *per se*; we will sum them out as a hidden variable when scoring a question-answer pair. Second, our probability model includes an optional mixture component that permits arbitrary features—we experiment with a small set of WordNet lexical-semantics features (see Section 4.4). Third, we apply a more discriminative training method (conditional maximum likelihood estimation, Section 4.5).

4 The Jeopardy Model

Our model, informally speaking, aims to follow the process a player of the television game show *Jeopardy!* might follow. The player knows the answer (or at least *thinks* he knows the answer) and must quickly turn it into a question.[2] The question-answer pairs used on *Jeopardy!* are not precisely what we have in mind for the real task (the questions are not specific enough), but the syntactic transformation inspires our model. In this section we formally define

[1] Smith and Eisner also show how QG formalisms generalize synchronous grammar formalisms.

[2] A round of *Jeopardy!* involves a somewhat involved and specific "answer" presented to the competitors, and the first competitor to hit a buzzer proposes the "question" that leads to the answer. For example, an answer might be, *This Eastern European capital is famous for defenestrations.* In *Jeopardy!* the players must respond with a queston: *What is Prague?*

this probability model and present the necessary algorithms for parameter estimation.

4.1 Probabilistic Model

The Jeopardy model is a QG designed for QA. Let $\mathbf{q} = \langle q_1, ..., q_n \rangle$ be a question sentence (each q_i is a word), and let $\mathbf{a} = \langle a_1, ..., a_m \rangle$ be a candidate answer sentence. (We will use $\mathbf{w}$ to denote an abstract sequence that could be a question or an answer.) In practice, these sequences may include other information, such as POS, but for clarity we assume just words in the exposition. Let $\mathcal{A}$ be the set of candidate answers under consideration. Our aim is to choose:

$$\hat{\mathbf{a}} = \operatorname*{argmax}_{\mathbf{a} \in \mathcal{A}} p(\mathbf{a} \mid \mathbf{q}) \tag{1}$$

At a high level, we make three adjustments. The first is to apply Bayes' rule, $p(\mathbf{a} \mid \mathbf{q}) \propto p(\mathbf{q} \mid \mathbf{a}) \cdot p(\mathbf{a})$. Because $\mathcal{A}$ is known and is assumed to be generated by an external extraction system, we could use that extraction system to assign scores (and hence, probabilities $p(\mathbf{a})$) to the candidate answers. Other scores could also be used, such as reputability of the document the answer came from, grammaticality, etc. Here, aiming for simplicity, we do not aim to use such information. Hence we treat $p(\mathbf{a})$ as uniform over $\mathcal{A}$.[3]

The second adjustment adds a labeled, directed **dependency tree** to the question and the answer. The tree is produced by a state-of-the-art dependency parser (McDonald et al., 2005) trained on the *Wall Street Journal* Penn Treebank (Marcus et al., 1993). A dependency tree on a sequence $\mathbf{w} = \langle w_1, ..., w_k \rangle$ is a mapping of indices of words to indices of their syntactic parents and a label for the syntactic relation, $\tau : \{1, ..., k\} \rightarrow \{0, ..., k\} \times \mathcal{L}$. Each word w_i has a single parent, denoted $w_{\tau(i).par}$. Cycles are not permitted. w_0 is taken to be the invisible "wall" symbol at the left edge of the sentence; it has a single child ($|\{i : \tau(i) = 0\}| = 1$). The label for w_i is denoted $\tau(i).lab$.

The third adjustment involves a hidden variable X, the **alignment** between question and answer words. In our model, each question-word maps to exactly one answer-word. Let $x : \{1, ..., n\} \rightarrow \{1, ..., m\}$ be a mapping from indices of words in $\mathbf{q}$ to indices of words in $\mathbf{a}$. (It is for computational reasons that we assume $|x(i)| = 1$; in general x could range over *subsets* of $\{1, ..., m\}$.) Because we define the correspondence in this direction, note that it is possible for multple question words to map to the same answer word.

Why do we treat the alignment X as a hidden variable? In prior work, the alignment is assumed to be known given the sentences, but we aim to discover it from data. Our guide in this learning is the structure inherent in the QG: the configurations between parent-child pairs in the question and their corresponding, aligned words in the answer. The hidden variable treatment lets us avoid commitment to any one x mapping, making the method more robust to noisy parses (after all, the parser is not 100% accurate) and any wrong assumptions imposed by the model (that $|x(i)| = 1$, for example, or that syntactic transformations can explain the connection between $\mathbf{q}$ and $\mathbf{a}$ at all).[4]

Our model, then, defines

$$p(\mathbf{q}, \tau_{\mathbf{q}} \mid \mathbf{a}, \tau_{\mathbf{a}}) = \sum_x p(\mathbf{q}, \tau_{\mathbf{q}}, x \mid \mathbf{a}, \tau_{\mathbf{a}}) \tag{2}$$

where $\tau_{\mathbf{q}}$ and $\tau_{\mathbf{a}}$ are the question tree and answer tree, respectively. The stochastic process defined by our model factors cleanly into recursive steps that derive the question from the top down. The QG defines a grammar for this derivation; the grammar depends on the specific answer.

Let $\tau_{\mathbf{w}}^i$ refer to the subtree of $\tau_{\mathbf{w}}$ rooted at w_i. The model is defined by:

$$\begin{aligned}
& p(\tau_{\mathbf{q}}^i \mid q_i, \tau_{\mathbf{q}}(i), x(i), \tau_{\mathbf{a}}) = \qquad (3) \\
& \quad p_{\#kids}(|\{j : \tau_{\mathbf{q}}(j) = i, j < i\}| \mid q_i, \mathit{left}) \\
& \quad \times p_{\#kids}(|\{j : \tau_{\mathbf{q}}(j) = i, j > i\}| \mid q_i, \mathit{right}) \\
& \quad \times \prod_{j : \tau_{\mathbf{q}}(j) = i} \sum_{x(j)=0}^{m} \\
& \qquad\quad p_{kid}(q_j, \tau_{\mathbf{q}}(j).lab \mid q_i, \tau_{\mathbf{q}}(i), x(i), x(j), \tau_{\mathbf{a}}) \\
& \qquad\quad \times p(\tau_{\mathbf{q}}^j \mid q_j, \tau_{\mathbf{q}}(j), x(j), \tau_{\mathbf{a}})
\end{aligned}$$

[3] The main motivation for modeling $p(\mathbf{q} \mid \mathbf{a})$ is that it is easier to model *deletion* of information (such as the part of the sentence that answers the question) than *insertion*. Our QG does not model the real-world knowledge required to fill in an answer; its job is to know what answers are likely to look like, syntactically.

[4] If parsing performance is a concern, we might also treat the question and/or answer parse trees as hidden variables, though that makes training and testing more computationally expensive.

Note the recursion in the last line. While the above may be daunting, in practice it boils down only to defining the conditional distribution p_{kid}, since the number of left and right children of each node need not be modeled (the trees are assumed known)—$p_{\#kids}$ is included above for completeness, but in the model applied here we do not condition it on q_i and therefore do not need to estimate it (since the trees are fixed).

p_{kid} defines a distribution over syntactic children of q_i and their labels, given (1) the word q_i, (2) the parent of q_i, (3) the dependency relation between q_i and its parent, (4) the answer-word q_i is aligned to, (5) the answer-word the *child* being predicted is aligned to, and (6) the remainder of the answer tree.

4.2 Dynamic Programming

Given $\mathbf{q}$, the score for an answer is simply $p(\mathbf{q}, \tau_{\mathbf{q}} \mid \mathbf{a}, \tau_{\mathbf{a}})$. Computing the score requires summing over alignments and can be done efficiently by bottom-up dynamic programming. Let $S(j, \ell)$ refer to the score of $\tau_{\mathbf{q}}^j$, assuming that the parent of q_j, $\tau_{\mathbf{q}}(j).par$, is aligned to a_ℓ. The base case, for leaves of $\tau_{\mathbf{q}}$, is:

$$\begin{aligned} &S(j, \ell) = \qquad (4)\\ &\quad p_{\#kids}(0 \mid q_j, \mathit{left}) \times p_{\#kids}(0 \mid q_j, \mathit{right})\\ &\quad \times \sum_{k=0}^{m} p_{kid}(q_j, \tau_{\mathbf{q}}(j).lab \mid q_{\tau_{\mathbf{q}}(j)}, \ell, k, \tau_{\mathbf{a}}) \end{aligned}$$

Note that k ranges over indices of answer-words to be aligned to q_j. The recursive case is

$$\begin{aligned} &S(i, \ell) = \qquad (5)\\ &\quad p_{\#kids}(|\{j : \tau_{\mathbf{q}}(j) = i, j < i\}| \mid q_j, \mathit{left})\\ &\quad \times p_{\#kids}(|\{j : \tau_{\mathbf{q}}(j) = i, j > i\}| \mid q_j, \mathit{right})\\ &\quad \times \sum_{k=0}^{m} p_{kid}(q_i, \tau_{\mathbf{q}}(i).lab \mid q_{\tau_{\mathbf{q}}(i)}, \ell, k, \tau_{\mathbf{a}})\\ &\qquad \times \prod_{j : \tau_{\mathbf{q}}(j) = i} S(j, k) \end{aligned}$$

Solving these equations bottom-up can be done in $O(nm^2)$ time and $O(nm)$ space; in practice this is very efficient. In our experiments, computing the value of a question-answer pair took two seconds on average.[5] We turn next to the details of p_{kid}, the core of the model.

4.3 Base Model

Our base model factors p_{kid} into three conditional multinomial distributions.

$$\begin{aligned} &p_{kid}^{base}(q_i, \tau_{\mathbf{q}}(i).lab \mid q_{\tau_{\mathbf{q}}(i)}, \ell, k, \tau_{\mathbf{a}}) =\\ &\quad p(q_i.pos \mid a_k.pos) \times p(q_i.ne \mid a_k.ne)\\ &\quad \times p(\tau_{\mathbf{q}}(i).lab \mid \mathit{config}(\tau_{\mathbf{q}}, \tau_{\mathbf{a}}, i)) \qquad (6) \end{aligned}$$

where $q_i.pos$ is question-word i's POS label and $q_i.ne$ is its named-entity label. *config* maps question-word i, its parent, and their alignees to a QG configuration as described in Table 1; note that some configurations are extended with additional tree information. The base model does not directly predict the specific words in the question—only their parts-of-speech, named-entity labels, and dependency relation labels. This model is very similar to Smith and Eisner (2006).

Because we are interested in augmenting the QG with additional lexical-semantic knowledge, we also estimate p_{kid} by **mixing** the base model with a model that exploits WordNet (Miller et al., 1990) lexical-semantic relations. The mixture is given by:

$$p_{kid}(\bullet \mid \bullet) = \alpha p_{kid}^{base}(\bullet \mid \bullet) + (1-\alpha) p_{kid}^{ls}(\bullet \mid \bullet) \qquad (7)$$

4.4 Lexical-Semantics Log-Linear Model

The lexical-semantics model p_{kid}^{ls} is defined by predicting a (nonempty) subset of the thirteen classes for the question-side word given the identity of its aligned answer-side word. These classes include WordNet relations: identical-word, synonym, antonym (also extended and indirect antonym), hypernym, hyponym, derived form, morphological variation (e.g., plural form), verb group, entailment, entailed-by, see-also, and causal relation. In addition, to capture the special importance of Wh-words in questions, we add a special semantic relation called "q-word" between any word and any Wh-word. This is done through a log-linear model with one feature per relation. Multiple relations may fire, motivating the log-linear model, which permits "overlapping" features, and, therefore prediction of

[5] Experiments were run on a 64-bit machine with 2× 2.2GHz dual-core CPUs and 4GB of memory.

any of the possible $2^{13} - 1$ nonempty subsets. It is important to note that this model assigns zero probability to alignment of an answer-word with any question-word that is *not* directly related to it through *any* relation. Such words may be linked in the mixture model, however, via p_{kid}^{base}.[6]

(It is worth pointing out that log-linear models provide great flexibility in defining new features. It is straightforward to extend the feature set to include more domain-specific knowledge or other kinds of morphological, syntactic, or semantic information. Indeed, we explored some additional syntactic features, fleshing out the configurations in Table 1 in more detail, but did not see any interesting improvements.)

parent-child	Question parent-child pair align respectively to answer parent-child pair. Augmented with the q.-side dependency label.
child-parent	Question parent-child pair align respectively to answer child-parent pair. Augmented with the q.-side dependency label.
grandparent-child	Question parent-child pair align respectively to answer grandparent-child pair. Augmented with the q.-side dependency label.
same node	Question parent-child pair align to the same answer-word.
siblings	Question parent-child pair align to siblings in the answer. Augmented with the tree-distance between the a.-side siblings.
c-command	The parent of one answer-side word is an ancestor of the other answer-side word.
other	A catch-all for all other types of configurations, which are permitted.

Table 1: Syntactic alignment configurations are partitioned into these sets for prediction under the Jeopardy model.

4.5 Parameter Estimation

The parameters to be estimated for the Jeopardy model boil down to the conditional multinomial distributions in p_{kid}^{base}, the log-linear weights inside of p_{kid}^{ls}, and the mixture coefficient α.[7] Standard applications of log-linear models apply conditional maximum likelihood estimation, which for our case involves using an empirical distribution $\tilde{p}$ over question-answer pairs (and their trees) to optimize as follows:

$$\max_{\theta} \sum_{\mathbf{q},\tau_{\mathbf{q}},\mathbf{a},\tau_{\mathbf{a}}} \tilde{p}(\mathbf{q},\tau_{\mathbf{q}},\mathbf{a},\tau_{\mathbf{a}}) \log \underbrace{p_{\theta}(\mathbf{q},\tau_{\mathbf{q}} \mid \mathbf{a},\tau_{\mathbf{a}})}_{\sum_x p_{\theta}(\mathbf{q},\tau_{\mathbf{q}},x|\mathbf{a},\tau_{\mathbf{a}})} \tag{8}$$

Note the hidden variable x being summed out; that makes the optimization problem non-convex. This sort of problem can be solved in principle by conditional variants of the Expectation-Maximization algorithm (Baum et al., 1970; Dempster et al., 1977; Meng and Rubin, 1993; Jebara and Pentland, 1999). We use a quasi-Newton method known as L-BFGS (Liu and Nocedal, 1989) that makes use of the gradient of the above function (straightforward to compute, but omitted for space).

5 Experiments

To evaluate our model, we conducted experiments using Text REtrieval Conference (TREC) 8–13 QA dataset.[8]

5.1 Experimental Setup

The TREC dataset contains questions and answer patterns, as well as a pool of documents returned by participating teams. Our task is the same as Punyakanok et al. (2004) and Cui et al. (2005), where we search for single-sentence answers to factoid questions. We follow a similar setup to Shen and Klakow (2006) by automatically selecting answer candidate sentences and then comparing against a human-judged gold standard.

We used the questions in TREC 8–12 for training and set aside TREC 13 questions for development (84 questions) and testing (100 questions). To generate the candidate answer set for *development* and *testing*, we automatically selected sentences from each question's document pool that contains one or more non-stopwords from the question. For generating the training candidate set, in addtion to the sentences that contain non-stopwords from the question, we also added sentences that contain correct

[6] It is to preserve that robustness property that the models are *mixed*, and not combined some other way.

[7] In our experiments, all log-linear weights are initialized to be 1; all multinomial distributions are initialized as uniform distributions; α is initialized to be 0.1.

[8] We thank the organizers and NIST for making the dataset publicly available.

answer pattern. Manual judgement was produced for the entire TREC 13 set, and also for the first 100 questions from the training set TREC 8–12.[9] On average, each question in the development set has 3.1 positive and 17.1 negative answers. There are 3.6 positive and 20.0 negative answers per question in the test set.

We tokenized sentences using the standard treebank tokenization script, and then we performed part-of-speech tagging using MXPOST tagger (Ratnaparkhi, 1996). The resulting POS-tagged sentences were then parsed using MSTParser (McDonald et al., 2005), trained on the entire Penn Treebank to produce labeled dependency parse trees (we used a coarse dependency label set that includes twelve label types). We used BBN Identifinder (Bikel et al., 1999) for named-entity tagging.

As answers in our task are considered to be single sentences, our evaluation differs slightly from TREC, where an answer string (a word or phrase like *1977* or *George Bush*) has to be accompanied by a supporting document ID. As discussed by Punyakanok et al. (2004), the single-sentence assumption does not simplify the task, since the hardest part of answer finding is to locate the correct sentence. From an end-user's point of view, presenting the sentence that contains the answer is often more informative and evidential. Furthermore, although the judgement data in our case are more labor-intensive to obtain, we believe our evaluation method is a better indicator than the TREC evaluation for the quality of an answer selection algorithm.

To illustrate the point, consider the example question, "*When did James Dean die?*" The correct answer as appeared in the sentence "*In 1955, actor James Dean was killed in a two-car collision near Cholame, Calif.*" is *1955*. But from the same document, there is another sentence which also contains *1955*: "*In 1955, the studio asked him to become a technical adviser on Elia Kazan's 'East of Eden,' starring James Dean.*" If a system missed the first sentence but happened to have extracted *1955* from the second one, the TREC evaluation grants it a "correct and well-supported" point, since the document ID matches the correct document ID—even though the latter answer does not entail the true answer. Our evaluation does not suffer from this problem.

We report two standard evaluation measures commonly used in IR and QA research: mean average precision (MAP) and mean reciprocal rank (MRR). All results are produced using the standard `trec_eval` program.

5.2 Baseline Systems

We implemented two state-of-the-art answer-finding algorithms (Cui et al., 2005; Punyakanok et al., 2004) as strong baselines for comparison. Cui et al. (2005) is the answer-finding algorithm behind one of the best performing systems in TREC evaluations. It uses a mutual information-inspired score computed over dependency trees and a single alignment between them. We found the method to be brittle, often not finding a score for a testing instance because alignment was not possible. We extended the original algorithm, allowing fuzzy word alignments through WordNet expansion; both results are reported.

The second baseline is the approximate tree-matching work by Punyakanok et al. (2004). Their algorithm measures the similarity between $\tau_{\mathbf{q}}$ and $\tau_{\mathbf{a}}$ by computing tree edit distance. Our replication is close to the algorithm they describe, with one subtle difference. Punyakanok et al. used answer-typing in computing edit distance; this is not available in our dataset (and our method does not explicitly carry out answer-typing). Their heuristics for reformulating questions into statements were not replicated. We did, however, apply WordNet type-checking and approximate, penalized lexical matching. Both results are reported.

[9] More human-judged data are desirable, though we will address training from noisy, *automatically* judged data in Section 5.4. It is important to note that human judgement of answer sentence correctness was carried out prior to any experiments, and therefore is unbiased. The total number of questions in TREC 13 is 230. We exclude from the TREC 13 set questions that either have no correct answer candidates (27 questions), or no incorrect answer candidates (19 questions). Any algorithm will get the same performance on these questions, and therefore obscures the evaluation results. 6 such questions were also excluded from the 100 manually-judged training questions, resulting in 94 questions for training. For computational reasons (the cost of parsing), we also eliminated answer candidate sentences that are longer than 40 words from the training and evaluation set. After these data preparation steps, we have 348 positive Q-A pairs for training, 1,415 Q-A pairs in the development set, and 1,703 Q-A pairs in the test set.

		development set		test set	
training dataset	model	MAP	MRR	MAP	MRR
100 manually-judged	TreeMatch	0.4074	0.4458	0.3814	0.4462
	+WN	0.4328	0.4961	0.4189	0.4939
	Cui et al.	0.4715	0.6059	0.4350	0.5569
	+WN	0.5311	0.6162	0.4271	0.5259
	Jeopardy (base only)	0.5189	0.5788	0.4828	0.5571
	Jeopardy	**0.6812**	**0.7636**	**0.6029**	**0.6852**
+2,293 noisy	Cui et al.	0.2165	0.3690	0.2833	0.4248
	+WN	0.4333	0.5363	0.3811	0.4964
	Jeopardy (base only)	0.5174	0.5570	0.4922	0.5732
	Jeopardy	0.6683	0.7443	0.5655	0.6687

Table 2: Results on development and test sets. TreeMatch is our implementation of Punyakanok et al. (2004); +WN modifies their edit distance function using WordNet. We also report our implementation of Cui et al. (2005), along with our WordNet expansion (+WN). The Jeopardy base model and mixture with the lexical-semantics log-linear model perform best; both are trained using conditional maximum likelihood estimation. The top part of the table shows performance using 100 manually-annotated question examples (questions 1–100 in TREC 8–12), and the bottom part adds noisily, automatically annotated questions 101–2,393. Boldface marks the best score in a column and any scores in that column not significantly worse under a a two-tailed paired t-test ($p < 0.03$).

5.3 Results

Evaluation results on the development and test sets of our model in comparison with the baseline algorithms are shown in Table 2. Both our model and the model in Cui et al. (2005) are trained on the manually-judged training set (questions 1-100 from TREC 8–12). The approximate tree matching algorithm in Punyakanok et al. (2004) uses fixed edit distance functions and therefore does not require training. From the table we can see that our model significantly outperforms the two baseline algorithms—even when they are given the benefit of WordNet—on both development and test set, and on both MRR and MAP.

5.4 Experiments with Noisy Training Data

Although manual annotation of the remaining 2,293 training sentences' answers in TREC 8–12 was too labor-intensive, we did experiment with a simple, noisy automatic labeling technique. Any answer that had at least three non-stop word types seen in the question *and* contains the answer pattern defined in the dataset was labeled as "correct" and used in training. The bottom part of Table 2 shows the results. Adding the noisy data hurts all methods, but the Jeopardy model maintains its lead and consistently suffers less damage than Cui et al. (2005). (The TreeMatch method of Punyakanok et al. (2004) does not use training examples.)

5.5 Summing vs. Maximizing

Unlike most previous work, our model does not try to find a single correspondence between words in the question and words in the answer, during training or during testing. An alternative method might choose the *best* (most probable) alignment, rather than the sum of all alignment scores. This involves a slight change to Equation 3, replacing the summation with a maximization. The change could be made during training, during testing, or both. Table 3 shows that summing is preferable, especially during training.

6 Discussion

The key experimental result of this work is that loose syntactic transformations are an effective way to carry out statistical question answering.

One unique advantage of our model is the mixture of a factored, multinomial-based base model and a potentially very rich log-linear model. The base model gives our model robustness, and the log-

		test set	
training	decoding	MAP	MRR
Σ	Σ	**0.6029**	**0.6852**
Σ	$\max$	0.5822	0.6489
$\max$	Σ	0.5559	0.6250
$\max$	$\max$	0.5571	0.6365

Table 3: Experimental results on comparing summing over alignments (Σ) with maximizing ($\max$) over alignments on the test set. Boldface marks the best score in a column and any scores in that column not significantly worse under a a two-tailed paired t-test ($p < 0.03$).

linear model allows us to throw in task- or domain-specific features. Using a mixture gives the advantage of smoothing (in the base model) without having to normalize the log-linear model by summing over large sets. This powerful combination leads us to believe that our model can be easily ported to other semantic processing tasks where modeling syntactic and semantic transformations is the key, such as textual entailment, paraphrasing, and cross-lingual QA.

The traditional approach to cross-lingual QA is that translation is either a pre-processing or post-processing step done independently from the main QA task. Notice that the QG formalism that we have employed in this work was originally proposed for machine translation. We might envision transformations that are performed together to form questions from answers (or vice versa) *and* to translate—a *Jeopardy!* game in which bilingual players must ask a question in a different language than that in which the answer is posed.

7 Conclusion

We described a statistical syntax-based model that softly aligns a question sentence with a candidate answer sentence and returns a score. Discriminative training and a relatively straightforward, barely-engineered feature set were used in the implementation. Our scoring model was found to greatly outperform two state-of-the-art baselines on an answer selection task using the TREC dataset.

Abstract

Previous machine learning techniques for answer selection in question answering (QA) have required question-answer training pairs. It has been too expensive and labor-intensive, however, to collect these training pairs. This paper presents a novel unsupervised support vector machine (U-SVM) classifier for answer selection, which is independent of language and does not require hand-tagged training pairs. The key ideas are the following: 1. unsupervised learning of training data for the classifier by clustering web search results; and 2. selecting the correct answer from the candidates by classifying the question. The comparative experiments demonstrate that the proposed approach significantly outperforms the retrieval-based model (Retrieval-M), the supervised SVM classifier (S-SVM), and the pattern-based model (Pattern-M) for answer selection. Moreover, the cross-model comparison showed that the performance ranking of these models was: U-SVM > Pattern-M > S-SVM > Retrieval-M.

1 Introduction

The purpose of answer selection in QA is to select the exact answer to the question from the extracted candidate answers. In recent years, many supervised machine learning techniques for answer selection in open-domain question answering have been investigated in some pioneering studies [Ittycheriah et al. 2001; Ng et al. 2001; Suzuki et al. 2002; Sasaki, et al. 2005; and Echihabi et al. 2003]. Compared with retrieval-based [Yang et al. 2003], pattern-based [Ravichandran et al. 2002 and Soubbotin et al. 2002], and deep NLP-based [Moldovan et al. 2002, Hovy et al. 2001; and Pasca et al. 2001] answer selection, machine learning techniques are more effective in constructing QA components from scratch. These techniques suffer, however, from the problem of requiring an adequate number of hand-tagged question-answer training pairs. It is too expensive and labor intensive to collect such training pairs for supervised machine learning techniques.

To tackle this knowledge acquisition bottleneck, this paper presents an unsupervised SVM classifier for answer selection, which is independent of language and question type, and avoids the need for hand-tagged question-answer pairs. The key ideas are as follows:

1. Regarding answer selection as a kind of classification task and adopting an SVM classifier;

2. Applying unsupervised learning of pseudo-training data for the SVM classifier by clustering web search results;

3. Training the SVM classifier by using three types of features extracted from the pseudo-training data; and

4. Selecting the correct answer from the candidate answers by classifying the question. Note that this means classifying a question into one of the clusters learned by clustering web search results. Therefore, our classifying the question

Proceedings of the 2007 Joint Conference on Empirical Methods in Natural Language Processing and Computational Natural Language Learning, pp. 33–41, Prague, June 2007. ©2007 Association for Computational Linguistics

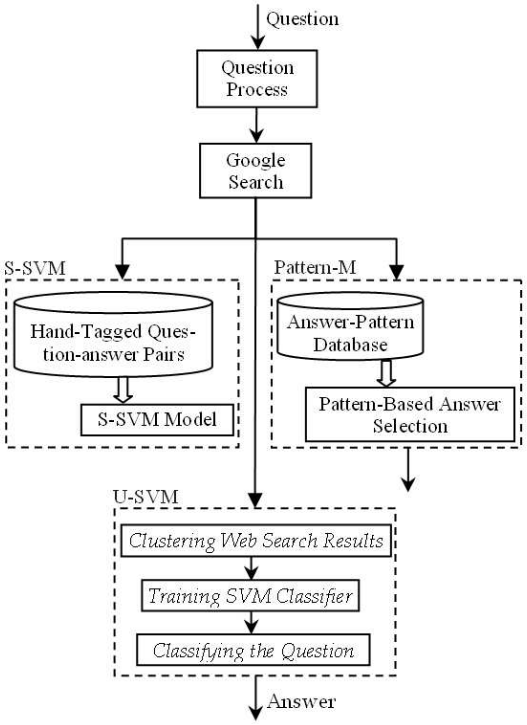

Figure 1: Web Question Answering Architecture

> is different from conventional question classification (QC) [Li et al. 2002] that determines the answer type of the question.

The proposed approach is fully unsupervised and starts only from a user question. It does not require richly annotated corpora or any deep linguistic tools. To the best of our knowledge, no research on this kind of study we discuss here has been reported. Figure 1 illustrates the architecture of our web QA approach. The S-SVM and Pattern-M models are included for comparison.

Because the focus of this paper just evaluates the answer selection part, our approach requires knowledge of the answer type to the question in order to find candidate answers, and that the answer must be a NE for convenience in candidate extraction. Experiments using Chinese versions of the TREC 2004 and 2005 test data sets show that our approach significantly outperforms the S-SVM for answer selection, with a top_1 score improvement of more than 20%. Results obtained with the test data set in [Wu et al. 2004] show that the U-SVM increases the $top\_1/mrr\_5/top\_5$ scores by 5.95%/6.06%/8.68% as compared with the Pattern-M. Moreover, our cross-model comparison demonstrates that the performance ranking of all models considered is: U-SVM $>$ Pattern-M $>$ S-SVM $>$ Retrieval-M.

2 Comparison among Models

Related researches on answer selection in QA can be classified into four categories. The retrieval-based model [Yang et al. 2003] selects a correct answer from the candidates according to the distance between a candidate and all question keywords. This model does not work, however, if the question and the answer-bearing sentences do not match on the surface. The pattern-based model [Ravichandran et al. 2002 and Soubbotin et al. 2002] first classifies the question into predefined categories, and then extracts the exact answer by using answer patterns learned off-line. Although the pattern-based model can obtain high precision for some predefined types of questions, it is difficult to define question types in advance for open-domain question answering. Furthermore, this model is not suitable for all types of questions. The deep NLP-based model [Moldovan et al. 2002; Hovy et al. 2001; and Pasca et al. 2001] usually parses the user question and an answer-bearing sentence into a semantic representation, and then semantically matches them to find the answer. This model has performed very well at TREC workshops, but it heavily depends on high-performance NLP tools, which are time consuming and labor intensive for many languages. Finally, the machine learning-based model has also been investigated. current models of this type are based on supervised approaches [Ittycheriah et al. 2001; Ng et al. 2001; Suzuki et al. 2002; and Sasaki et al. 2005] that are heavily dependent on hand-tagged question-answer training pairs, which not readily available.

In response to this situation, this paper presents the U-SVM for answer selection in open-domain web question answering system. Our U-SVM has the following advantages over supervised machine learning techniques. First, the U-SVM classifies questions into a question-dependent set of clusters, and the answer is the name of a question cluster. In contrast, most previous models have classified candidates into positive and negative. Second, the U-SVM automatically learns the unique question-dependent clusters and the pseudo-training for each

Table 1: Comparison of Various Machine Learning Techniques

System	Model	Key Idea	Training Data
[Ittycheriah et al. 2001]	ME Classifier	Classifying candidates into positive and negative	5,000 English Q-A pairs
[Suzuki et al. 2002]	SVM Classifier	Classifying candidates into positive and negative	1358 Japanese Q-A pairs
[Echihabi et al. 2003]	N-C Model	Selecting correct answer by aligning question with sentences	90,000 English Q-A pairs
[Sasaki et al. 2005]	ME Classifier	Classifying words in sentences into answer and non-answer words	2,000 Japanese Q-A pairs
Our U-SVM Model	SVM Classifier	Classifying question into a set of question-dependent clusters	No Q-A pairs

question. This differs from the supervised techniques, in which a large number of hand-tagged training pairs are shared by all of the test questions. In addition, supervised techniques independently process the answer-bearing sentences, so the answers to the questions may not always be extractable because of algorithmic limitations. On the other hand, the U-SVM can use the interdependence between answer-bearing sentences to select the answer to a question.

Table 1 compares the key idea and training data used in the U-SVM with those used in the supervised machine learning techniques. Here, ME means the maximum entropy model, and N-C means the noisy-channel model.

3 The U-SVM

The essence of the U-SVM is to regard answer selection as a kind of text categorization-like classification task, but with no training data available. In the U-SVM, the steps of ”clustering web search results”, ”classifying the question”, and ”training SVM classifier” play very important roles.

3.1 Clustering Web Search Results

Web search results, such as snippets returned by Google, usually include a mixture of multiple subtopics (called clusters in this paper) related to the user question. To group the web search results into clusters, we assume that the candidate answer in each Google snippet can represent the ”signature” of its cluster. In other words, the Google snippets containing the same candidate are regarded as aligned snippets, and thus belong to the same cluster. Web search results are clustered in two phases.

- A first-stage Google search (FGS) is applied to extract n candidate answers $\{c_1, c_2, \ldots, c_n\}$ from the top m Google snippets $\{s_1, s_2, \ldots, s_m\}$ by a NER tool [Wu et al. 2005]. Those snippets containing the candidates $\{c_i\}$ and at least one question keyword $\{q_i\}$ are retained. Finally, the retained snippets $\{s_1, s_2, \ldots, s_m\}$ are clustered into n clusters $\{C_1, C_2, \ldots, C_n\}$ by clustering web search results, that is,

  If a snippet includes L different candidates, the snippet belongs to L different clusters.
  If the candidates of different snippets are the same, these snippets belong to the same clusters.

  Consequently, the number of clusters $\{C_i\}$ is fully determined by the number of candidates $\{c_i\}$, and the cluster name of a cluster C_i is the candidate answer c_i. Up to this point, we have obtained clusters and sample snippets for each cluster that will be used as training data for the SVM classifier. Because this training data is learned automatically, rather than hand-tagged, we call it pseudo-training data.

- A second-stage Google search (SGS) is applied to resolve data sparseness in the pseudo-training samples learned through the FGS. The FGS data may have very few training snippets in some clusters, so more snippets must be collected. Note that this step just learns new

Google snippets into the clusters learned by the FGS, but does not add new clusters.

```
For each candidate answer $c_i$:
    Combine the original query $q = \{q_i\}$ and
    the candidate $c_i$ to form a new query $q\prime =$
    $\{q, c_i\}$.
    Submit $q\prime$ to Google and download the top
    50 Google snippets.
    Retain the snippets containing the candi-
    date $c_i$ and at least one keyword $q_i$.
    Group the retained snippets into $n$ clusters
    to form the new pseudo-training data.
End
```

Here, we give an example illustrating the principle of clustering web search results in the FGS. In submitting TREC 2004 test question 1.1 ”when was the first Crip gang started?” to Google (*http://www.google.com/apis*), we extract $n(= 8)$ different candidates from the top $m(= 30)$ Google snippets. The Google snippets containing the same candidates are aligned snippets, and thus the 12 retained snippets are grouped into 8 clusters, as listed in Table 2. This table roughly indicates that the snippets with the same candidate answers contain the same sub-meanings, so these snippets are considered as aligned snippets. For example, all Google snippets that contain the candidate answer *1969* express the time of establishment of ”the first Crip gang”.

In summary, the U-SVM uses the result of ”clustering web search results” as the pseudo-training data of the SVM classifier, and then classifies user question into one of the clusters for answer selection. On the one hand, the clusters and their names are based on candidate answers to question; on the other hand, candidates are dependent on question. Therefore, the clusters are question-dependent.

3.2 Classifying Question

Using the pseudo-training data obtained by clustering web search results to train the SVM classifier, we classify user questions into a set of question-dependent clusters and assume that the correct answer is the name of the question cluster that is assigned by the trained U-SVM classifier. For the above example, if the U-SVM classifier, trained on the pseudo-training data listed in Table 2, classifies the above test question into a cluster whose name is *1969*, then the cluster name *1969* is the answer to the question.

This paper selects LIBSVM toolkit[1] to implement the SVM classifier. The kernel is the radical basis function with the parameter $\gamma = 0.001$ in the experiments.

3.3 Feature Extraction

To classify the question into a question-dependent set of clusters, the U-SVM classifier extracts three types of features.

- A similarity-based feature set (SBFS) is extracted from the Google snippets. The SBFS attempts to capture the word overlap between a question and a snippet. The possible values range from 0 to 1.

SBFS Features
percentage of matched keywords (KWs)
percentage of mismatched KWs
percentage of matched bi-grams of KWs
percentage of matched thesauruses
normalized distance between candidate and KWs

To compute the matched thesaurus feature, we adopt TONGYICICILIN [2] in the experiments.

- A Boolean match-based feature set (BMFS) is also extracted from the Google snippets. The BMFS attempts to capture the specific keyword Boolean matches between a question and a snippet. The possible values are true or false.

BMFS Features
person names are matched or not
location names are matched or not
organization names are matched or not
time words are matched or not
number words are matched or not
root verb is matched or not
candidate has or does not have bi-gram in snippet matching bi-gram in question
candidate has or does not have desired named entity type

- A window-based word feature set (WWFS) is a set of words consisting of the words

preceding $\{w_{i-5}, \ldots, w_{i-1}\}$ and following $\{w_{i+1}, \ldots, w_{i+5}\}$ the candidate answer. The WWFS features can be regarded as a kind of relevant snippets-based question keywords expansion. By extracting the WWFS feature set, the feature space in the U-SVM becomes question dependent, which may be more suitable for classifying the question. The number of classification features in the S-SVM must be fixed, however, because all questions share the same training data. This is one difference between the U-SVM and the supervised SVM classifier for answer selection. Each word feature in the WWFS is weighted using its ISF value.

$$ISF(w_j, C_i) = \frac{N(w_j, C_i) + 0.5}{N(w_j) + 0.5} \qquad (1)$$

where $N(w_j)$ is the total number of the snippets containing word feature w_j, and $N(w_j, C_i)$ is the number of snippets in cluster C_i containing word feature w_j.

When constructing question vector, we assume that the question is an ideal question that contains all the extracted WWFS words. Therefore, the values of the WWFS word features in question vector are 1. Similarly, the values of the SBFS and BMFS features in question vector are also estimated by self-similarity calculation.

4 Experiments

4.1 Data Sets

For the experiments, no English named entity recognition (NER) tool is in our hand at the time of the experiments; therefore, we validate the U-SVM in terms of Chinese web QA using three test data sets, which will be published with this paper[3]. Although the U-SVM is independent of the question types, for convenience in candidate extraction, only those questions whose answers are named entities are selected. The three test data sets are CTREC04, CTREC05 and CTEST05. CTREC04 is a set of 178 Chinese questions translated from TREC 2004 FACTOID testing questions. CTREC05 is a set of 279 Chinese questions translated from TREC 2005 FACTOID testing questions. CTEST05 is a set of 178 Chinese questions found in [Wu et al. 2004] that are similar to TREC testing questions except that they are written in Chinese. Figure 2 breaks down the types of questions (manually assigned) in the CTREC04 and CTREC05 data sets. Here, PER, LOC, ORG, TIM, NUM, and CR refer to questions whose answers are a person, location, organization, time, number, and book or movie, respectively.

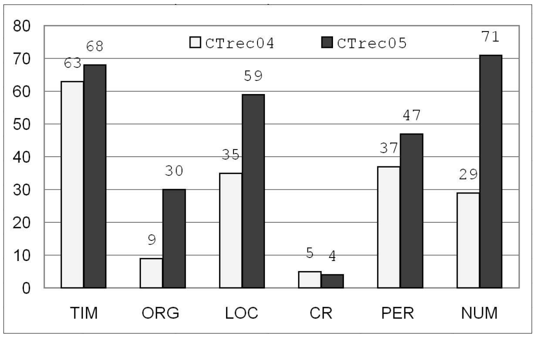

Figure 2: Statistics of CTEST05

To collect the question-answer training data for the S-SVM, we submitted 807 Chinese questions to Google and extracted the candidates for each question from the top *50* Google snippets. We then manually selected the snippets containing the correct answers as positive snippets, and designated all of the other snippets as negative snippets. Finally, we collected 807 hand-tagged Chinese question-answer pairs as the training data of S-SVM called CTRAINDATA.

4.2 Evaluation Method

In the experiments, the top $m(=50)$ Google snippets are adopted to extract candidates by using a Chinese NER tool [Wu et al. 2005]. The number of the candidates extracted from the top $m(=50)$ snippets, n, is adaptive for different questions but it does not exceed 30. The results are evaluated in terms of two scores, top_n and mrr_5. Here, top_n is the rate at which at least one correct answer is included in the top n answers, while mrr_5 is the average reciprocal rank $(1/n)$ of the highest rank $n(n \leq 5)$ of a correct answer to each question.

4.3 U-SVM vs. Retrieval-M

The Retrieval-M selects the candidate with the shortest distances to all question keywords as the correct answer. In this experiment, the Retrieval-M is implemented based on the snippets returned by Google, while the U-SVM is based on the SGS data, the SBFS and BMFS feature. Table 3 summarizes the comparative performance.

Table 3: Comparison of Retrieval-M and U-SVM

		Retrieval-M	U-SVM
CTREC04	top_1	27.84%	53.61%
	mrr_5	43.67%	66.25%
	top_5	71.13%	88.66%
CTREC05	top_1	34.00%	50.00%
	mrr_5	48.20%	62.38%
	top_5	71.33%	82.67%

The table shows that the U-SVM greatly improves the performance of the Retrieval-M: the top_1 improvements for CTREC04 and CTREC05 are about 25.8% and 16.0%, respectively. This experiment demonstrates that the assumptions used here in clustering web search results and in classifying the question are effective in many cases, and that the U-SVM benefits from these assumptions.

4.4 U-SVM vs. S-SVM

To explore the effectiveness of our unsupervised model as compared with the supervised model, we conduct a cross-model comparison of the S-SVM and the U-SVM with the SBFS and BMFS feature sets. The U-SVM results are compared with the S-SVM results for CTREC04 and CTREC05 in Tables 4 and 5, respectively. The S-SVM is trained on CTRAINDATA.

These tables show the following:

[3] Currently no public testing question set for simplified Chinese QA is available.

Table 4: Comparison of U-SVM and S-SVM on CTREC04

		FGS	SGS
top_1	S-SVM	30.93%	39.18%
	U-SVM	45.36%	53.61%
mrr_1	S-SVM	45.36%	53.54%
	U-SVM	57.44%	66.25%
top_5	S-SVM	71.13%	79.38%
	U-SVM	76.29%	88.66%

Table 5: Comparison of U-SVM and S-SVM on CTREC05

		FGS	SGS
top_1	S-SVM	30.00%	33.33%
	U-SVM	48.00%	50.00%
mrr_1	S-SVM	45.59%	48.67%
	U-SVM	58.01%	62.38%
top_5	S-SVM	72.00%	74.67%
	U-SVM	75.33%	82.67%

- The proposed U-SVM significantly outperforms the S-SVM for all measurements and all test data sets. For the CTREC04 test data set, the top_1 improvements for the FGS and SGS data are about 14.5% and 14.4%, respectively. For the CTREC05 test data set, the top_1 score for the FGS data increases from 30.0% to 48.0%, and the top_1 score for the SGS data increases from 33.3% to 50.0%. Note that the SBFS and BMFS features here is fewer than the features in [Ittycheriah et al. 2001; Suzuki et al. 2002], but the comparison is still effective because the models are compared in terms of the same features. In the S-SVM, all questions share the same training data, while the U-SVM uses the unique pseudo-training data for each question. This is the main reason why the U-SVM performs better than the S-SVM does.

- The SGS data is greatly helpful for both the U-SVM and the S-SVM. Compared with the FGS data, the $top\_1/mrr\_5/top\_5$ improvements for the S-SVM and the U-SVM on CTREC04 are 8.25%/8.18%/8.25% and 7.25%/8.81%/12.37%. The SGS can be regarded as a kind of query expansion. The reasons for this improvement are: the data sparseness in FGS data is partially resolved; and the use of the Web to introduce data redundancy is helpful. [Clarke et al. 2001; Magnini et al. 2002; and Dumais et al. 2002].

In the S-SVM, all of the test questions share the same hand-tagged training data, so the WWFS features cannot be easily used [Ittycheriah et al. 2002; Suzuki, et al. 2002]. Tables 6 and 7 compare the performances of the U-SVM with the (SBFS + BMFS) features, the WWFS features, and combination of three types of features for the CTREC04 and CTREC05 test data sets, respectively.

Table 6: Performances of U-SVM for Different Features on CTREC04

	SBFS+BMFS	WWFS	Combination
top_1	53.61%	46.39%	60.82%
mrr_5	66.25%	59.19%	71.31%
top_5	88.66%	81.44%	88.66%

Table 7: Performances of U-SVM for Different Features on CTREC05

	SBFS+BMFS	WWFS	Combination
top_1	50.00%	49.33%	57.33%
mrr_5	62.38%	59.26%	65.61%
top_5	82.67%	74.00%	80.00%

These tables report that combining three types of features can improve the performance of the U-SVM. Using a combination of features with the CTREC04 test data set results in the best performances: 60.82%/71.31%/88.66% for $top\_1/mrr\_5/top\_5$. Similarly, as compared with using the (SBFS + BMFS) and WWFS features, the improvements from using a combination of features with the CTREC05 test data set are 7.33%/3.23%/-2.67% and 8.00%/6.35%/6.00%, respectively. The results also demonstrate that the (SBFS + BMFS) features are more important than the WWFS features.

These comparative experiments indicate that the U-SVM performs better than the S-SVM does, even though the U-SVM is an unsupervised technique and no hand-tagged training data is provided. The average top_1 improvements for both test data sets are both more than 20%.

4.5 U-SVM vs. Pattern-M vs. S-SVM

To compare the U-SVM with the Pattern-M and the S-SVM, we use the CTEST05 data set, shown in Figure 3. The CTEST05 includes 14 different question types, for example, Inventor_Stuff (with question like "Who invented telephone?"), Event-Day (with question like "when is World Day for Water?"), and so on. The Pattern-M uses the dependency syntactic answer patterns learned in [Wu et al. 2007] to extract the answer, and named entities are also used to filter noise from the candidates.

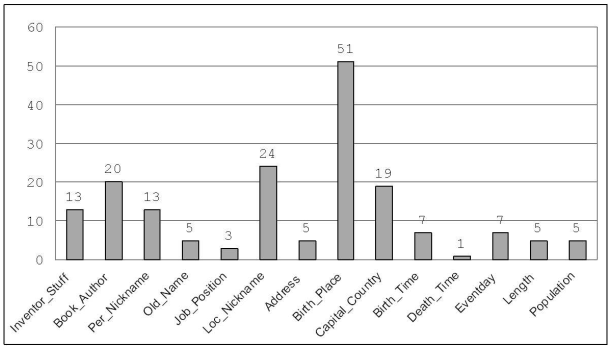

Figure 3: Statistics of CTEST05

Table 8 summarizes the performances of the U-SVM, Pattern-M, and S-SVM models on CTEST05.

Table 8: Comparison of U-SVM, Pattern-M and S-SVM on CTEST05

	S-SVM	Pattern-M	U-SVM
top_1	44.89%	53.14%	59.09%
mrr_5	56.49%	61.28%	67.34%
top_5	74.43%	73.14%	81.82%

The results in the table show that the U-SVM significantly outperforms the S-SVM and Pattern-M, while the S-SVM underperforms the Pattern-M. Compared with the Pattern-M, the U-SVM increases the $top\_1/mrr\_5/top\_5$ scores by 5.95%/ 6.06%/8.68%, respectively. The reasons may lie in the following:

- The Chinese dependency parser influences dependency syntactic answer-pattern extraction, and thus degrades the performance of the Pattern-M model.
- The imperfection of Google snippets affects pattern matching, and thus adversely influences the Pattern-M model. From the cross-model comparison, we conclude that the performance ranking of these models is: U-SVM $>$ Pattern-M $>$ S-SVM $>$ Retrieval-M.

5 Conclusion and Future Work

This paper presents an unsupervised machine learning technique (called the U-SVM) for answer selection that is validated in Chinese open-domain web QA. Regarding answer selection as a kind of classification task, the U-SVM automatically learns clusters and pseudo-training data for each cluster by clustering web search results. It then selects the correct answer from the candidates according to classifying the question. The contribution of this paper is that it presents an unsupervised machine learning technique for web QA that starts with only a user question. The results of our experiments with three test data sets are encouraging. As compared with the S-SVM, the top_1 performances of the U-SVM for the CTREC04 and CTREC05 data sets are significantly improved, at more than 20%. Moreover, the U-SVM performs better than the Retrieval-M and the Pattern-M.

These experiments have only validated the U-SVM on named entity types of questions that account for about 82% of all TREC2004 and 2005 FACTOID test questions. In fact, our technique is independent of question types only if the candidates can be extracted. In the future, we will explore the effectiveness of our technique for the other types of questions. The web search results clustering in the U-SVM defines that a candidate in a Google snippet can represent the "signature" of its cluster. This definition, however, is not always effective. To filter noise in the pseudo-training data, we will extract relations between the candidates and the keywords as the cluster signatures of Google snippets. Moreover, applying the U-SVM to QA systems in other languages, like English and Japanese, will also be included in our future work.

Abstract

We describe an approach to improve Statistical Machine Translation (SMT) performance using multi-lingual, parallel, sentence-aligned corpora in several bridge languages. Our approach consists of a simple method for utilizing a bridge language to create a word alignment system and a procedure for combining word alignment systems from multiple bridge languages. The final translation is obtained by consensus decoding that combines hypotheses obtained using all bridge language word alignments. We present experiments showing that multilingual, parallel text in Spanish, French, Russian, and Chinese can be utilized in this framework to improve translation performance on an Arabic-to-English task.

1 Introduction

Word Alignment of parallel texts forms a crucial component of phrase-based statistical machine translation systems. High quality word alignments can yield more accurate phrase-pairs which improve quality of a phrase-based SMT system (Och and Ney, 2003; Fraser and Marcu, 2006b).

Much of the recent work in word alignment has focussed on improving the word alignment quality through better modeling (Och and Ney, 2003; Deng and Byrne, 2005; Martin et al., 2005) or alternative approaches to training (Fraser and Marcu, 2006b; Moore, 2005; Ittycheriah and Roukos, 2005). In this paper we explore a complementary approach to improve word alignments using multi-lingual, parallel (or multi-parallel) corpora. Two works in the literature are very relevant to our approach. Borin (2000) describes a non-statistical approach where a pivot alignment is used to combine direct translation and indirect translation via a third language. Filali and Bilmes (2005) present a multi-lingual extension to the IBM/HMM models. Our current approach differs from this latter work in that we propose a simple framework to combine word alignments from any underlying statistical alignment model without the need for changing the structure of the model. While both of the above papers focus on improving word alignment quality, we demonstrate that our approach can yield improvements in translation performance. In particular, we aim to improve an Arabic-to-English (Ar-En) system using multi-parallel data from Spanish (Es), French (Fr), Russian (Ru) and Chinese (Zh). The parallel data in these languages $X \in \{Es, Fr, Ru, Zh\}$ is used to generate word alignments between Arabic-X and X-English. These alignments are then combined to obtain multiple word alignments for Arabic-English and the final translation systems.

The motivation for this approach is two-fold. First, we believe that parallel corpora available in several languages provide a better training material for SMT systems relative to bilingual corpora. Such multi-lingual parallel corpora are becoming widely available; examples include proceedings of the United Nations in six languages (UN, 2006), European Parliament (EU, 2005; Koehn, 2003), JRC Acquis corpus (EU, 2007) and religious texts (Resnik et al., 1997). Word alignment systems

Proceedings of the 2007 Joint Conference on Empirical Methods in Natural Language Processing and Computational Natural Language Learning, pp. 42–50, Prague, June 2007. ©2007 Association for Computational Linguistics

trained on different language-pairs (e.g. French-English versus Russian-English) make errors which are somewhat orthogonal. In such cases, incorrect alignment links between a sentence-pair can be corrected when a translation in a third language is available. Thus it can help resolve errors in word alignment. We combine word alignments using several bridge languages with the aim of correcting some of the alignment errors. The second advantage of this approach is that the word alignment from each bridge language can be utilized to build a phrase-based SMT system. This provides a diverse collection of translation hypotheses for MT system combination (Bangalore et al., 2002; Sim et al., 2007; Matusov et al., 2006; Macherey and Och, 2007). Finally, a side benefit of this paper is that it provides a study that compares alignment qualities and BLEU scores for models in different languages trained on parallel text which is held identical across all languages.

We show that parallel corpora in multiple languages can be exploited to improve the translation performance of a phrase-based translation system. This paper gives specific recipes for using a bridge language to construct a word alignment and for combining word alignments produced by multiple statistical alignment models.

The rest of this paper is organized as follows: Section 2 gives an overview of our framework for generating word alignments in a single language-pair. In Section 3, we describe how a bridge language may be used for producing word alignments. In Section 4, we describe a scheme to combine word alignments from several bridge languages. Section 5 describes our experimental setup and reports the alignment and translation performance. A final discussion is presented in Section 6.

2 Word Alignment Framework

A statistical translation model (Brown et al., 1993; Och and Ney, 2003) describes the relationship between a pair of sentences in the source and target languages ($\mathbf{f} = f_1^J, \mathbf{e} = e_1^I$) using a translation probability $P(\mathbf{f}|\mathbf{e})$. Alignment models introduce a hidden alignment variable $\mathbf{a} = a_1^J$ to specify a mapping between source and target words; $a_j = i$ indicates that the j^{th} source word is linked to the i^{th} target word. Alignment models assign a probability $P(\mathbf{f}, \mathbf{a}|\mathbf{e})$ to the source sentence and alignment conditioned on the target sentence. The translation probability is related to the alignment model as: $P(\mathbf{f}|\mathbf{e}) = \sum_{\mathbf{a}} P_\theta(\mathbf{f}, \mathbf{a}|e)$, where θ is a set of parameters.

Given a sentence-pair $(\mathbf{f}, \mathbf{e})$, the most likely (Viterbi) word alignment is found as (Brown et al., 1993): $\hat{\mathbf{a}} = \text{argmax}_{\mathbf{a}} P(\mathbf{f}, \mathbf{a}|\mathbf{e})$. An alternate criterion is the Maximum A-Posteriori (MAP) framework (Ge, 2004; Matusov et al., 2004). We use a refinement of this technique.

Given any word alignment model, posterior probabilities can be computed as (Brown et al., 1993)

$$P(a_j = i|\mathbf{e}, \mathbf{f}) = \sum_{\mathbf{a}} P(\mathbf{a}|\mathbf{f}, \mathbf{e})\delta(i, a_j), \qquad (1)$$

where $i \in \{0, 1, ..., I\}$. The assignment $a_j = 0$ corresponds to the NULL (empty) alignment. These posterior probabilities form a matrix of size $(I+1) \times J$, where entries along each column sum to one.

The MAP alignment for each source position $j \in \{1, 2, ..., J\}$ is then computed as

$$a_{MAP}(j) = \underset{i}{\text{argmax}}\, P(a_j = i|\mathbf{e}, \mathbf{f}). \qquad (2)$$

We note that these posterior probabilities can be computed efficiently for some alignment models such as the HMM (Vogel et al., 1996; Och and Ney, 2003), Models 1 and 2 (Brown et al., 1993).

In the next two sections, we describe how posterior probabilities can be used to a) construct alignment systems from a bridge language, and b) merge several alignment systems.

3 Constructing Word Alignment Using a Bridge Language

We assume here that we have triples of sentences that are translations of each other in languages F, E, and the bridge language G: $\mathbf{f} = f_1^J, \mathbf{e} = e_1^I, \mathbf{g} = g_1^K$. Our goal is to obtain posterior probability estimates for the sentence-pair in FE: $(\mathbf{f}, \mathbf{e})$ using the posterior probability estimates for the sentence pairs in FG: $(\mathbf{f}, \mathbf{g})$ and GE: $(\mathbf{g}, \mathbf{e})$. The word alignments between the above sentence-pairs are referred to as $\mathbf{a}^{FE}$, $\mathbf{a}^{FG}$, and $\mathbf{a}^{GE}$ respectively; the notation $\mathbf{a}^{FE}$ indicates that the alignment maps a position in F to a position in E.

We first express the posterior probability as a sum over all possible translations g in G and hidden alignments a^{FG}.

$$\begin{aligned}
& P(a_j^{FE} = i|\mathbf{e}, \mathbf{f}) \\
= & \sum_{\mathbf{g}} P(a_j^{FE} = i, \mathbf{g}|\mathbf{e}, \mathbf{f}) \\
= & \sum_{\mathbf{g},k} P(a_j^{FE} = i, \mathbf{g}, a_j^{FG} = k|\mathbf{e}, \mathbf{f}) \\
= & \sum_{\mathbf{g},k} \Big\{ P(\mathbf{g}|\mathbf{e}, \mathbf{f}) P(a_j^{FG} = k|\mathbf{g}, \mathbf{e}, \mathbf{f}) \\
& \times P(a_j^{FE} = i|a_j^{FG} = k, \mathbf{g}, \mathbf{e}, \mathbf{f}) \Big\} \qquad (3)
\end{aligned}$$

We now make some assumptions to simplify the above expression. First, there is exactly one translation g in bridge language G corresponding to the sentence-pair $\mathbf{f}, \mathbf{e}$. Since $a^{GE}_{a^{FG}_j} = i = a^{FE}_j$, we can express
$P(a_j^{FE} = i|a_j^{FG} = k, \mathbf{g}, \mathbf{f}, \mathbf{e}) = P(a_k^{GE} = i|\mathbf{g}, \mathbf{e})$.
Finally, alignments in FG do not depend on E.

Under these assumptions, we arrive at the final expression for the posterior probability FE in terms of posterior probabilities for GF and EG

$$\begin{aligned}
& P(a_j^{FE} = i|\mathbf{e}, \mathbf{f}) = \qquad (4) \\
& \sum_{k=0}^{K} P(a_j^{FG} = k|\mathbf{g}, \mathbf{f}) P(a_k^{GE} = i|\mathbf{g}, \mathbf{e})
\end{aligned}$$

The above expression states that the posterior probability matrix for FE can be obtained using a *simple matrix multiplication* of posterior probability matrices for GE and FG. In this multiplication, we prepend a column to the GE matrix corresponding to $k = 0$. This probability $P(a_k^{GE} = i)$ when $k = 0$ is not assigned by the alignment model; we set it as follows

$$P(a_k^{GE} = i|k = 0) = \begin{cases} \epsilon & i = 0 \\ \frac{1-\epsilon}{I} & i \in \{1, 2, ..., I\} \end{cases}$$

The parameter ϵ controls the number of empty alignments; a higher value favors more empty alignments and vice versa. In our experiments, we set $\epsilon = 0.5$.

4 Word Alignment Combination Using Posterior Probabilities

We next show how Word Alignment Posterior Probabilities can be used for combining multiple word alignment systems. In our context, we use this procedure to combine word alignments produced using multiple bridge languages.

Suppose we have translations in bridge languages $G_1, G_2, ..., G_N$, we can generate a posterior probability matrix for FE using each of the bridge languages. In addition, we can always generate a posterior probability matrix for FE with the FE alignment model directly without using any bridge language. These $N + 1$ posterior matrices can be combined as follows. Here, the variable B indicates the bridge language. $B \in \{G_0, G_1, ..., G_N\}$; G_0 indicates the case when no bridge language is used.

$$\begin{aligned}
& P(a_j^{FE} = i|\mathbf{e}, \mathbf{f}) \qquad (5) \\
= & \sum_{l=0}^{N} P(B = G_l, a_j^{FE} = i|\mathbf{e}, \mathbf{f}) \\
= & \sum_{l=0}^{N} P(B = G_l) P(a_j^{FE} = i|G_l, \mathbf{e}, \mathbf{f}),
\end{aligned}$$

where $P(a_j^{FE} = i|G_l, j, \mathbf{e}, \mathbf{f})$ is the posterior probability when bridge language $B = G_l$. The probabilities $P(B = G_l)$ sum to one over $l \in \{0, 1, 2, ..., N\}$ and represent the prior probability of bridge language l. In our experiments, we use a uniform prior $P(B = G_l) = \frac{1}{N+1}$. Equation 5 provides us a way to combine word alignment posterior probabilites from multiple bridge languages. In our alignment framework (Section 2), we first interpolate the posterior probability matrices (Equation 5) and then extract the MAP word alignment (Equation 2) from the resulting matrix.

5 Experiments

We now present experiments to demonstrate the advantages of using bridge languages. Our experiments are performed in the open data track of the NIST Arabic-to-English (A-E) machine translation task [1].

5.1 Training and Test Data

Our approach to word alignment (Section 3) requires aligned sentences in multiple languages. For training alignment models, we use the ODS United Na-

[1] http://www.nist.gov/speech/tests/mt/

Set	# of Ar words (K)	# of sentences
dev1	48.6	2007
dev2	11.4	498
test	37.8	1610
blind	36.5	1797

Table 1: Statistics for the test data.

tions parallel data (UN, 2006) which contains parliamentary documents from 1993 onwards in all six official languages of the UN: Arabic (Ar), Chinese (Zh), English (En), French (Fr), Russian (Ru), and Spanish (Es).

We merge the NIST 2001-2005 Arabic-English evaluation sets into a pool and randomly sample this collection to create two development sets (dev1,dev2) and a test set (test) with 2007, 498, and 1610 sentences respectively. Our blind test (blind) set is the NIST part of the NIST 06 evaluation set consisting of 1797 sentences. The GALE portion of the 06 evaluation set is not used in this paper. We report results on the test and blind sets. Some statistics computed on the test data are shown in Table 1.

5.2 Alignment Model Training

For training Arabic-English alignment models, we use Chinese, French, Russian and Spanish as bridge languages. We train a model for Ar-En and 4 models each for Ar-X and X-En, where X is the bridge language. To obtain aligned sentences in these language pairs, we train 9 sentence aligners. We then train alignment models for all 9 language-pairs using a recipe consisting of 6 Model-1 iterations and 6 HMM iterations. Finally, Word Alignment Posterior Probabilities are generated over the bitext. In Table 2, we report the perplexities of the alignment models for the translation directions where either Arabic or English is predicted. There are 55M Arabic tokens and 58M English tokens. We observe that the alignment model using Spanish achieves the lowest perplexity; this value is even lower than the perplexity of the direct Arabic-English model. Perplexity is related to the hardness of the word alignment; the results suggest that bridge languages such as Spanish make alignment task easier while others do not. We stress that perplexity is not related to the alignment or the translation performance.

Bridge	Perplexity	
Lang	→ Ar	→En
None	113.8	26.1
Es	99.0	22.9
Fr	138.6	30.2
Ru	128.3	27.5
Zh	126.1	34.6

Table 2: Perplexities of the alignment models.

5.3 Bridge Language Word Alignments

Each of the 4 bridge languages is utilized for constructing a word alignment for Arabic-English. Using each bridge language X, we obtain Arabic-English word alignments in both translation directions (AE and EA). The posterior matrix for AE is obtained using AX and XE matrices while the EA matrix is obtained from EX and XA matrices (Equation 4). The AE (EA) matrices from the bridge languages are then interpolated with the AE (EA) matrix obtained from the alignment model trained directly on Arabic-English (Section 4). The MAP word alignment for AE (EA) direction is computed from the AE (EA) matrix. We next outline how these word alignments are utilized in building a phrase-based SMT system.

5.4 Phrase-based SMT system

Our phrase-based SMT system is similar to the alignment template system described in Och and Ney (2004). We first extract an inventory of phrase-pairs up to length 7 from the union of AE and EA word alignments. Various feature functions (Och and Ney, 2004) are then computed over the entries in the phrase table. 5-gram word language models in English are trained on a variety of monolingual corpora (Brants et al., 2007). Minimum Error Rate Training (MERT) (Och, 2003) under BLEU criterion is used to estimate 20 feature function weights over the larger development set (dev1).

Translation is performed using a standard dynamic programming beam-search decoder (Och and Ney, 2004). Decoding is done in two passes. An initial list of 1000-best hypotheses is generated by the decoder. This list is then rescored using Minimum Bayes-Risk (MBR) decoding (Kumar and Byrne, 2004). The MBR scaling parameter is tuned on the smaller development set (dev2).

Bridge Language	Metrics(%)					
	AE			EA		
	Prec	Rec	AER	Prec	Rec	AER
None	74.1	73.9	26.0	67.3	57.7	37.9
Es	61.7	56.3	41.1	50.0	40.2	55.4
Fr	52.9	48.0	49.7	42.3	33.6	62.5
Ru	57.4	50.8	46.1	40.2	31.6	64.6
Zh	44.3	39.3	58.3	39.7	29.9	65.9
AC1	70.0	65.0	32.6	56.8	46.4	48.9

Table 3: Alignment Performance with Bridge Languages

5.5 Alignment Results

We first report alignment performance (Table 3) of the alignment models obtained using the bridge languages. Alignment results are reported in terms of Precision (Prec), Recall (Rec) and Alignment Error Rate (AER). We report these numbers on a 94-sentence test set with translations in all six languages and human word alignments in Arabic-English. Our human word alignments do not distinguish between *Sure* and *Probable* links (Och and Ney, 2003).

In these experiments, we first identify the common subset of sentences which have translations in all six languages. Each of the 9 alignment models is then trained on this subset. We report Alignment performance in both translation directions: Arabic-to-English (AE) and English-to-Arabic (EA). The first row (None) gives the results when no bridge language is used.

Among the bridge languages, Spanish gives the best alignment for Arabic-English while Chinese results in the worst. This might be related to how different the bridge language is relative to either English or Arabic. The last row (AC1) shows the performance of the alignment obtained by combining None/Es/Fr/Ru/Zh alignments. This alignment outperforms all bridge alignments but is weaker than the alignment without any bridge language. Our hypothesis is that a good choice of interpolation weights (Equation 5) would reduce AER of the AC1 combination. However, we did not investigate these choices in this paper. We report alignment error rates here to give the readers an idea of the vastly different alignment performance using each of the bridge languages.

5.6 Translation Results

We now report translation performance of our techniques. We measure performance using the NIST implementation of case sensitive BLEU-4 on true-cased translations. We observed in experiments not reported here that results are almost identical with/without Minimum Error Rate Training ; we therefore report the results without the training. We note that the blind set is the NIST subset of the 2006 NIST evaluation set. The systems reported here are for the Unlimited Data Track in Arabic-to-English and obtain competitive performance relative to the results reported on the NIST official results page [2]

We present three sets of experiments. In Table 4, we describe the first set where all 9 alignment models are trained on nearly the same set of sentences (1.9M sentences, 57.5M words in English). This makes the alignment models in all bridge languages comparable. In the first row marked None, we do not use a bridge language. Instead, an Ar-En alignment model is trained directly on the set of sentence pairs. The next four rows give the performance of alignment models trained using the bridge languages Es, Fr, Ru and Zh respectively. For each language, we use the procedure (Section 3) to obtain the posterior probability matrix for Arabic-English from Arabic-X and X-English matrices. The row AC1 refers to alignment combination using interpolation of posterior probabilities described in Section 4. We combine posterior probability matrices from the systems in the first four rows: None, Es, Ru and Zh. We exclude the Zh system from the AC1 combination because it is found to degrade the translation performance by 0.2 points on the test set.

In the final six rows of Table 4, we show the performance of a consensus decoding technique that produces a single output hypothesis by combining translation hypotheses from multiple systems; this is an MBR-like candidate selection procedure based on BLEU correlation matrices and is described in Macherey and Och (2007). We first report performance of the consensus output by combining None systems with/without MERT. Each of the following rows provides the results from consensus decoding for adding an extra system both with/without MERT. Thus, the final row (TC1) combines transla-

[2] http://www.nist.gov/speech/tests/mt/mt06eval_official_results.html

tions from 12 systems: None, Es, Fr, Ru, Zh, AC1 with/without MERT. All entries marked with an asterisk are better than the None baseline with 95% statistical significance computed using paired bootstrap resampling (Koehn, 2004).

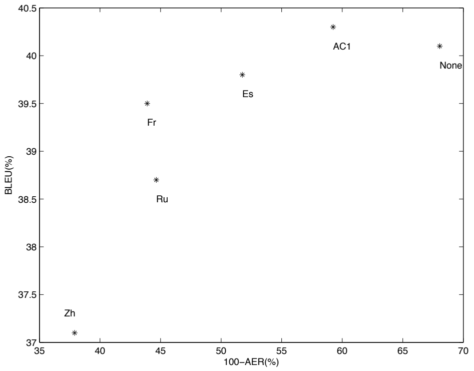

Figure 1: 100-AER (%) vs. BLEU(%) on the blind set for 6 systems from Table 3.

Figure 1 shows the plot between 100-AER% (average of EA/AE directions) and BLEU for the six systems in Table 3. We observe that AER is loosely correlated to BLEU ($\rho = 0.81$) though the relation is weak, as observed earlier by Fraser and Marcu (2006a). Among the bridge languages, Spanish gives the lowest AER/highest BLEU while Chinese results in highest AER/lowest BLEU. We can conclude that Spanish is closest to Arabic/English while Chinese is the farthest. All the bridge languages yield lower BLEU/higher AER relative to the No-Bridge baseline. Therefore, our estimate of the posterior probability (Equation 4) is always worse than the posterior probability obtained using a direct model. The alignment combination (AC1) behaves differently from other bridge systems in that it gives a higher AER and a higher BLEU relative to None baseline. We hypothesize that AC1 is different from the bridge language systems since it arises from a different process: interpolation with the direct model (None).

Both system combination techniques give improvements relative to None baseline: alignment combination AC1 gives a small gain (0.2 points) while the consensus translation TC1 results in a larger improvement (0.8 points). The last 4 rows of the table show that the performance of the hypothesis consensus steadily increases as systems get added to the None baseline. This shows that while bridge language systems are weaker than the direct model, they can provide complementary sources of evidence. To further validate this hypothesis, we compute inter-system BLEU scores between None/es and all the systems in Table 5. We observe that the baseline (None) is very dissimilar from the rest of the systems. We hypothesize that the baseline system has an alignment derived from a real alignment model while the rest of the bridge systems are derived using matrix multiplication. The low inter-system BLEU scores show that the bridge systems provide diverse hypotheses relative to the baseline and therefore contribute to gains in consensus decoding.

able in Ar, En and X. In Set 2, the first row (Union) is an alignment model trained on all sentence-pairs in Ar-En which are available in at least one bridge language X. AC2 refers to alignment combination using bridge languages Es/Fr/Ru and Union. TC2 refers to the translation combination from 12 systems: Es/Fr/Ru/Zh/Union/AC2 with/without Minimum Error Rate training. Finally, the goal in Set 3 (last 3 rows) is to improve the best Arabic-English system that can be built using all available sentence pairs from the UN corpus. The first row (Direct) gives the performance of this Ar-En system; AC3 refers to alignment combination using Es/Fr/Ru and Direct. TC3 merges translations from Es/Fr/Ru/Zh/Direct/AC3. All entries marked with an asterisk (plus) are better than the Union (Direct) baseline with 95% statistical significance computed using paired bootstrap resampling (Koehn, 2004).

The motivation behind Sets 2 and 3 is to train all bridge language systems on as much bitext as possible. As a consequence, these systems give better results than the corresponding systems in Table 4. The Union system outperforms None by 1.7/1.4 BLEU points and provides a better baseline. We show under this scenario that system combination techniques AC2 and TC2 can still give smaller improvements (0.3/0.5 and 1.0/0.7 points) relative to this baseline.

As mentioned earlier, our approach requires sentence-aligned corpora. In our experiments, we use a single sentence aligner for each language pair (total of 9 aligners). Since these aligners make independent decisions on sentence boundaries, we end up with a smaller pool of sentences (1.9M) that is common across all language pairs. In contrast, a sentence aligner that makes simultaneous decisions in multiple languages would result in a larger set of common sentence pairs (close to 7M sentence pairs). Simard (1999) describes a sentence aligner of this type that improves alignment on a trilingual parallel text. Since we do not currently have access to such an aligner, we simulate that situation with Sets 2 and 3: AC2/AC3 do not insist that a sentence-pair be present in all input word alignments. We note that Set 2 is a data scenario that falls between Sets 1 and 3.

Set 3 provides the best baseline for Arabic-English based on the UN data by training on all parallel sentence-pairs. In this situation, system combination with bridge languages (AC3/TC3) gives reasonable improvements in BLEU on the test set (0.4/1.0 points) but only modest improvements (0.1/0.4 points) on the blind set. However, this does show that the bridge systems continue to provide orthogonal evidence at different operating points.

6 Discussion

We have described a simple approach to improve word alignments using bridge languages. This includes two components: a matrix multiplication to assemble a posterior probability matrix for the desired language-pair FE using a pair of posterior probability matrices FG and GE relative to a bridge language G. The second component is a recipe for combining word alignment systems by linearly in-

terpolating posterior probability matrices from different sources. In our case, these sources are multiple bridge languages. However, this method is more generally applicable for combining posterior matrices from different alignment models such as HMM and Model-4. Such an approach contrasts with the log-linear HMM/Model-4 combination proposed by Och and Ney (2003).

There has been recent work by Ayan and Dorr (2006) on combining word alignments from different alignment systems; this paper describes a maximum entropy framework for this combination. Their approach operates at the level of the alignment links and uses maximum entropy to decide whether or not to include an alignment link in the final output. In contrast, we use posterior probabilities as the interface between different alignment models. Another difference is that this maxent framework requires human word aligned data for training feature weights. We do not require any human word aligned data to train our combiner.

Another advantage of our approach is that it is based on word alignment posterior probability matrices that can be generated by any underlying alignment model. Therefore, this method can be used to combine word alignments generated by fairly dissimilar word alignment systems as long as the systems can produce posterior probabilities.

Bridge languages have been used by NLP researchers as a means to induce translation lexicons between distant languages without the need for parallel corpora (Schafer and Yarowsky, 2002; Mann and Yarowsky, 2001). Our current approach differs from these efforts in that we use bridge languages to improve word alignment quality between sentence pairs. Furthermore, we do not use linguistic insight to identify bridge languages. In our framework, a good bridge language is one that provides the best translation performance using the posterior matrix multiplication. Our experiments show that Spanish is a better bridge language relative to Chinese for Arabic-to-English translation. We speculate that if our approach was carried out on a data set with hundreds of languages, we might be able to automatically identify language families.

A downside of our approach is the requirement for exact sentence-aligned parallel data. Except for a few corpora such as UN, European Parliament etc, such a resource is hard to find. One solution is to create such parallel data by automatic translation and then retaining reliable translations by using confidence metrics (Ueffing and Ney, 2005).

Our approach to using bridge languages is extremely simple. Despite its simplicity, the system combination gives improvements in alignment and translation performance. In future work, we will consider several extensions to this framework that lead to more powerful system combination strategies using multiple bridge languages. We recall that the present approach trains bridge systems (e.g. Arabic-to-French, French-to-English) until the alignment stage and then uses these for constructing Arabic-to-English word alignment. An alternate scenario would be to build phrase-based SMT systems for Arabic-to-Spanish and Spanish-to-English, and then obtain Arabic-to-English translation by first translating from Arabic into Spanish and then Spanish into English. Such end-to-end bridge systems may lead to an even more diverse pool of hypotheses that could further improve system combination.

Abstract

Word alignment is the problem of annotating parallel text with translational correspondence. Previous generative word alignment models have made structural assumptions such as the 1-to-1, 1-to-N, or phrase-based consecutive word assumptions, while previous discriminative models have either made such an assumption directly or used features derived from a generative model making one of these assumptions. We present a new generative alignment model which avoids these structural limitations, and show that it is effective when trained using both unsupervised and semi-supervised training methods.

1 Introduction

Several generative models and a large number of discriminatively trained models have been proposed in the literature to solve the problem of automatic word alignment of bitexts. The generative proposals have required unrealistic assumptions about the structure of the word alignments. Two assumptions are particularly common. The first is the 1-to-N assumption, meaning that each source word generates zero or more target words, which requires heuristic techniques in order to obtain alignments suitable for training a SMT system. The second is the consecutive word-based "phrasal SMT" assumption. This does not allow gaps, which can be used to particular advantage by SMT models which model hierarchical structure. Previous discriminative models have either made such assumptions directly or used features from a generative model making such an assumption. Our objective is to automatically produce alignments which can be used to build high quality machine translation systems. These are presumably close to the alignments that trained bilingual speakers produce. Human annotated alignments often contain M-to-N alignments, where several source words are aligned to several target words and the resulting unit can not be further decomposed. Source or target words in a single unit are sometimes nonconsecutive.

In this paper, we describe a new generative model which directly models M-to-N non-consecutive word alignments. The rest of the paper is organized as follows. The generative story is presented, followed by the mathematical formulation. Details of the unsupervised training procedure are described. The generative model is then decomposed into feature functions used in a log-linear model which is trained using a semi-supervised algorithm. Experiments show improvements in word alignment accuracy and usage of the generated alignments in hierarchical and phrasal SMT systems results in an increased BLEU score. Previous work is discussed and this is followed by the conclusion.

2 LEAF: a generative word alignment model

2.1 Generative story

We introduce a new generative story which enables the capture of non-consecutive M-to-N alignment structure. We have attempted to use the same labels as the generative story for Model 4 (Brown et

Proceedings of the 2007 Joint Conference on Empirical Methods in Natural Language Processing and Computational Natural Language Learning, pp. 51–60, Prague, June 2007. ©2007 Association for Computational Linguistics

al., 1993), which we are extending.

Our generative story describes the stochastic generation of a target string f (sometimes referred to as the French string, or foreign string) from a source string e (sometimes referred to as the English string), consisting of l words. The variable m is the length of f. We generally use the index i to refer to source words (e_i is the English word at position i), and j to refer to target words.

Our generative story makes the distinction between different types of source words. There are head words, non-head words, and deleted words. Similarly, for target words, there are head words, non-head words, and spurious words. A head word is linked to zero or more non-head words; each non-head word is linked to from exactly one head word. The purpose of head words is to try to provide a robust representation of the semantic features necessary to determine translational correspondence. This is similar to the use of syntactic head words in statistical parsers to provide a robust representation of the syntactic features of a parse sub-tree.

A minimal translational correspondence consists of a linkage between a source head word and a target head word (and by implication, the non-head words linked to them). Deleted source words are not involved in a minimal translational correspondence, as they were "deleted" by the translation process. Spurious target words are also not involved in a minimal translational correspondence, as they spontaneously appeared during the generation of other target words.

Figure 1 shows a simple example of the stochastic generation of a French sentence from an English sentence, annotated with the step number in the generative story.

1. Choose the source word type.

   for each $i = 1, 2, ..., l$ choose a word type $\chi_i = -1$ (non-head word), $\chi_i = 0$ (deleted word) or $\chi_i = 1$ (head word) according to the distribution $g(\chi_i|e_i)$

   let $\chi_0 = 1$

2. Choose the identity of the head word for each non-head word.

   for each $i = 1, 2, ..., l$ if $\chi_i = -1$ choose a "linked from head word" value μ_i (the position of the head word which e_i is linked to) according to the distribution $w_{-1}(\mu_i - i|\text{class}_e(e_i))$

   for each $i = 1, 2, ..., l$ if $\chi_i = 1$ let $\mu_i = i$

   for each $i = 1, 2, ..., l$ if $\chi_i = 0$ let $\mu_i = 0$

   for each $i = 1, 2, ..., l$ if $\chi_{\mu_i} \neq 1$ return "failure"

3. Choose the identity of the generated target head word for each source head word.

   for each $i = 1, 2, ..., l$ if $\chi_i = 1$ choose τ_{i1} according to the distribution $t_1(\tau_{i1}|e_i)$

4. Choose the number of words in a target cept conditioned on the identity of the source head word and the source cept size (γ_i is 1 if the cept size is 1, and 2 if the cept size is greater).

   for each $i = 1, 2, ..., l$ if $\chi_i = 1$ choose a Foreign cept size ψ_i according to the distribution $s(\psi_i|e_i, \gamma_i)$

   for each $i = 1, 2, ..., l$ if $\chi_i < 1$ let $\psi_i = 0$

5. Choose the number of spurious words.

   choose ψ_0 according to the distribution $s_0(\psi_0|\sum_i \psi_i)$

   let $m = \psi_0 + \sum_{i=1}^{l} \psi_i$

6. Choose the identity of the spurious words.

   for each $k = 1, 2, ..., \psi_0$ choose τ_{0k} according to the distribution $t_0(\tau_{0k})$

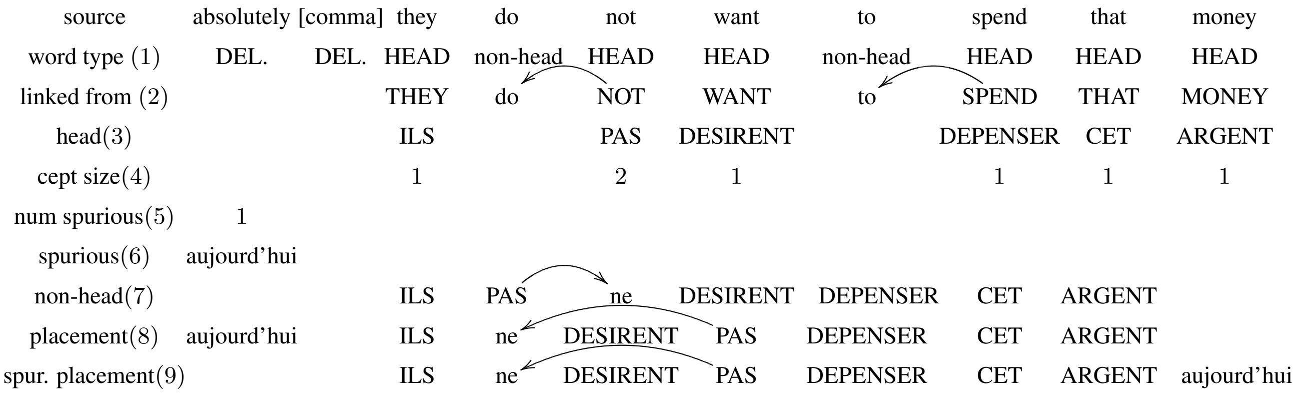
7. Choose the identity of the target non-head words linked to each target head word.

   for each $i = 1, 2, ..., l$ and for each $k = 2, 3, ..., \psi_i$ choose τ_{ik} according to the distribution $t_{>1}(\tau_{ik}|e_i, \text{class}_h(\tau_{i1}))$

8. Choose the position of the target head and non-head words.

   for each $i = 1, 2, ..., l$ and for each $k = 1, 2, ..., \psi_i$ choose a position π_{ik} as follows:

   - if $k = 1$ choose π_{i1} according to the distribution $d_1(\pi_{i1} - c_{\rho_i}|\text{class}_e(e_{\rho_i}), \text{class}_f(\tau_{i1}))$
   - if $k = 2$ choose π_{i2} according to the distribution $d_2(\pi_{i2} - \pi_{i1}|\text{class}_f(\tau_{i1}))$



source	absolutely	[comma]	they	do	not	want	to	spend	that	money

Figure 1: Generative story example, (number) indicates step number

- if $k > 2$ choose π_{ik} according to the distribution $d_{>2}(\pi_{ik} - \pi_{ik-1}|\text{class}_f(\tau_{i1}))$

if any position was chosen twice, return "failure"

9. Choose the position of the spuriously generated words.

   for each $k = 1, 2, ..., \psi_0$ choose a position π_{0k} from $\psi_0 - k + 1$ remaining vacant positions in $1, 2, ..., m$ according to the uniform distribution

   let f be the string $f\pi_{ik} = \tau_{ik}$

We note that the steps which return "failure" are required because the model is deficient. Deficiency means that a portion of the probability mass in the model is allocated towards generative stories which would result in infeasible alignment structures. Our model has deficiency in the non-spurious target word placement, just as Model 4 does. It has additional deficiency in the source word linking decisions. (Och and Ney, 2003) presented results suggesting that the additional parameters required to ensure that a model is not deficient result in inferior performance, but we plan to study whether this is the case for our generative model in future work.

Given e, f and a candidate alignment a, which represents both the links between source and target head-words and the head-word connections of the non-head words, we would like to calculate $p(f, a|e)$. The formula for this is:

$$
\begin{aligned}
p(f, a|e) =& [\prod_{i=1}^{l} g(\chi_i|e_i)] \\
& [\prod_{i=1}^{l} \delta(\chi_i, -1) w_{-1}(\mu_i - i|\text{class}_e(e_i))] \\
& [\prod_{i=1}^{l} \delta(\chi_i, 1) t_1(\tau_{i1}|e_i)] \\
& [\prod_{i=1}^{l} \delta(\chi_i, 1) s(\psi_i|e_i, \gamma_i)] \\
& [s_0(\psi_0|\sum_{i=1}^{l} \psi_i)] \\
& [\prod_{k=1}^{\psi_0} t_0(\tau_{0k})] \\
& [\prod_{i=1}^{l} \prod_{k=2}^{\psi_i} t_{>1}(\tau_{ik}|e_i, \text{class}_h(\tau_{i1}))] \\
& [\prod_{i=1}^{l} \prod_{k=1}^{\psi_i} D_{ik}(\pi_{ik})]
\end{aligned}
$$

where:

$\delta(i, i')$ is the Kronecker delta function which is equal to 1 if $i = i'$ and 0 otherwise.

ρ_i is the position of the closest English head word to the left of the word at i or 0 if there is no such word.

$\text{class}_e(e_i)$ is the word class of the English word at position i, $\text{class}_f(f_j)$ is the word class of the French word at position j, $\text{class}_h(f_j)$ is the word class of the French head word at position j.

p_0 and p_1 are parameters describing the probability of not generating and of generating a target spurious word from each non-spurious target word, $p_0 + p_1 = 1$.

$$m' = \sum_{i=1}^{l} \psi_i \tag{1}$$

$$s_0(\psi_0|m') = \binom{m'}{\psi_0} p_0^{m'-\psi_0} p_1^{\psi_0} \tag{2}$$

$$D_{ik}(j) = \begin{cases} d_1(j - c_{\rho_i}|\text{class}_e(e_{\rho_i}), \text{class}_f(\tau_{ik})) \\ \qquad \text{if } k = 1 \\ d_2(j - \pi_{i1}|\text{class}_f(\tau_{ik})) \\ \qquad \text{if } k = 2 \\ d_{>2}(j - \pi_{ik-1}|\text{class}_f(\tau_{ik})) \\ \qquad \text{if } k > 2 \end{cases} \tag{3}$$

$$\gamma_i = \min(2, \sum_{i'=1}^{l} \delta(\mu_{i'}, i)) \tag{4}$$

$$c_i = \begin{cases} \text{ceiling}(\sum_{k=1}^{\psi_i} \pi_{ik}/\psi_i) & \text{if } \psi_i \neq 0 \\ 0 & \text{if } \psi_i = 0 \end{cases} \tag{5}$$

The alignment structure used in many other models can be modeled using special cases of this framework. We can express the 1-to-N structure of models like Model 4 by disallowing $\chi_i = -1$, while for 1-to-1 structure we both disallow $\chi_i = -1$ and deterministically set $\psi_i = \chi_i$. We can also specialize our generative story to the consecutive word M-to-N alignments used in "phrase-based" models, though in this case the conditioning of the generation decisions would be quite different. This involves adding checks on source and target connection geometry to the generative story which, if violated, would return "failure"; naturally this is at the cost of additional deficiency.

2.2 Unsupervised Parameter Estimation

We can perform maximum likelihood estimation of the parameters of this model in a similar fashion to that of Model 4 (Brown et al., 1993), described thoroughly in (Och and Ney, 2003). We use Viterbi training (Brown et al., 1993) but neighborhood estimation (Al-Onaizan et al., 1999; Och and Ney, 2003) or "pegging" (Brown et al., 1993) could also be used.

To initialize the parameters of the generative model for the first iteration, we use bootstrapping from a 1-to-N and a M-to-1 alignment. We use the intersection of the 1-to-N and M-to-1 alignments to establish the head word relationship, the 1-to-N alignment to delineate the target word cepts, and the M-to-1 alignment to delineate the source word cepts.

In bootstrapping, a problem arises when we encounter infeasible alignment structure where, for instance, a source word generates target words but no link between any of the target words and the source word appears in the intersection, so it is not clear which target word is the target head word. To address this, we consider each of the N generated target words as the target head word in turn and assign this configuration 1/N of the counts.

For each iteration of training we search for the Viterbi solution for millions of sentences. Evidence that inference over the space of all possible alignments is intractable has been presented, for a similar problem, in (Knight, 1999). Unlike phrase-based SMT, left-to-right hypothesis extension using a beam decoder is unlikely to be effective because in word alignment reordering is not limited to a small local window and so the necessary beam would be very large. We are not aware of admissible or inadmissible search heuristics which have been shown to be effective when used in conjunction with a search algorithm similar to A* search for a model predicting over a structure like ours. Therefore we use a simple local search algorithm which operates on complete hypotheses.

(Brown et al., 1993) defined two local search operations for their 1-to-N alignment models 3, 4 and 5. All alignments which are reachable via these operations from the starting alignment are considered. One operation is to change the generation decision for a French word to a different English word (move), and the other is to swap the generation decision for two French words (swap). All possible operations are tried and the best is chosen. This is repeated. The search is terminated when no operation results in an improvement. (Och and Ney, 2003) discussed efficient implementation.

In our model, because the alignment structure is richer, we define the following operations: move French non-head word to new head, move English non-head word to new head, swap heads of two French non-head words, swap heads of two English non-head words, swap English head word links of two French head words, link English word to French word making new head words, unlink English and French head words. We use multiple restarts to try to reduce search errors. (Germann et al., 2004; Marcu and Wong, 2002) have some similar operations without the head word distinction.

3 Semi-supervised parameter estimation

Equation 6 defines a log-linear model. Each feature function h_m has an associated weight λ_m. Given a vector of these weights λ, the alignment search problem, i.e. the search to return the best alignment $\hat{a}$ of the sentences e and f according to the model, is specified by Equation 7.

$$p_\lambda(f,a|e) = \frac{\exp(\sum_m \lambda_m h_m(a,e,f))}{\sum_{a',f'} \exp(\sum_m \lambda_m h_m(a',e,f'))} \quad (6)$$

$$\hat{a} = \operatorname*{argmax}_a \sum_m \lambda_m h_m(f,a,e) \quad (7)$$

We decompose the new generative model presented in Section 2 in both translation directions to provide the initial feature functions for our log-linear model, features 1 to 10 and 16 to 25 in Table 1.

We use backoffs for the translation decisions (features 11 and 26 and the HMM translation tables which are features 12 and 27) and the target cept size distributions (features 13, 14, 28 and 29 in Table 1), as well as heuristics which directly control the number of unaligned words we generate (features 15 and 30 in Table 1).

We use the semi-supervised EMD algorithm (Fraser and Marcu, 2006b) to train the model. The initial M-step bootstraps parameters as described in Section 2.2 from a M-to-1 and a 1-to-N alignment. We then perform the D-step following (Fraser and Marcu, 2006b). Given the feature function parameters estimated in the M-step and the feature function weights λ determined in the D-step, the E-step searches for the Viterbi alignment for the full training corpus.

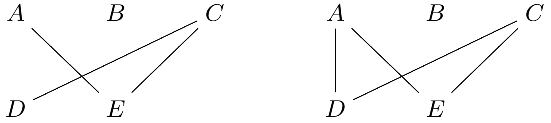

Figure 2: Two alignments with the same translational correspondence

We use $1 -$ F-Measure as our error criterion. (Fraser and Marcu, 2006a) established that it is important to tune α (the trade-off between Precision and Recall) to maximize performance. In working with LEAF, we discovered a methodological problem with our baseline systems, which is that two alignments which have the same translational correspondence can have different F-Measures. An example is shown in Figure 2.

To overcome this problem we fully interlinked the transitive closure of the undirected bigraph formed by each alignment hypothesized by our baseline alignment systems[1]. This operation maps the alignment shown to the left in Figure 2 to the alignment shown to the right. This operation does not change the collection of phrases or rules extracted from a hypothesized alignment, see, for instance, (Koehn et al., 2003). Working with this fully interlinked representation we found that the best settings of α were $\alpha = 0.1$ for the Arabic/English task and $\alpha = 0.4$ for the French/English task.

4 Experiments

4.1 Data Sets

We perform experiments on two large alignments tasks, for Arabic/English and French/English data sets. Statistics for these sets are shown in Table 2. All of the data used is available from the Linguistic Data Consortium except for the French/English

[1] All of the gold standard alignments were fully interlinked as distributed. We did not modify the gold standard alignments.

1	$chi(\chi_i \mid e_i)$ source word type	9	$d_2(\triangle j \mid \text{class}_f(f_j))$ movement for left-most target non-head word
2	$\mu(\triangle i \mid \text{class}_e(e_i))$ choosing a head word	10	$d_{>2}(\triangle j \mid \text{class}_f(f_j))$ movement for subsequent target non-head words
3	$t_1(f_j \mid e_i)$ head word translation	11	$t(f_j \mid e_i)$ translation without dependency on word-type
4	$s(\psi_i \mid e_i, \gamma_i)$ ψ_i is number of words in target cept	12	$t(f_j \mid e_i)$ translation table from final HMM iteration
5	$s_0(\psi_0 \mid \sum_i \psi_i)$ number of unaligned target words	13	$s(\psi_i \mid \gamma_i)$ target cept size without dependency on source head word e
6	$t_0(f_j)$ identity of unaligned target words	14	$s(\psi_i \mid e_i)$ target cept size without dependency on γ_i
7	$t_{>1}(f_j \mid e_i, \text{class}_h(\tau_{i1}))$ non-head word translation	15	target spurious word penalty
8	$d_1(\triangle j \mid \text{class}_e(e_\rho), \text{class}_f(f_j))$ movement for target head words	16-30	(same features, other direction)

Table 1: Feature functions

gold standard alignments which are available from the authors.

4.2 Experiments

To build all alignment systems, we start with 5 iterations of Model 1 followed by 4 iterations of HMM (Vogel et al., 1996), as implemented in GIZA++ (Och and Ney, 2003).

For all non-LEAF systems, we take the best performing of the "union", "refined" and "intersection" symmetrization heuristics (Och and Ney, 2003) to combine the 1-to-N and M-to-1 directions resulting in a M-to-N alignment. Because these systems do not output fully linked alignments, we fully link the resulting alignments as described at the end of Section 3. The reader should recall that this does not change the set of rules or phrases that can be extracted using the alignment.

We perform one main comparison, which is of semi-supervised systems, which is what we will use to produce alignments for SMT. We compare semi-supervised LEAF with a previous state of the art semi-supervised system (Fraser and Marcu, 2006b). We performed translation experiments on the alignments generated using semi-supervised training to verify that the improvements in F-Measure result in increases in BLEU.

We also compare the unsupervised LEAF system with GIZA++ Model 4 to give some idea of the performance of the unsupervised model. We made an effort to optimize the free parameters of GIZA++, while for unsupervised LEAF there are no free parameters to optimize. A single iteration of unsupervised LEAF[2] is compared with heuristic symmetrization of GIZA++'s extension of Model 4 (which was run for four iterations). LEAF was bootstrapped as described in Section 2.2 from the HMM Viterbi alignments.

Results for the experiments on the French/English data set are shown in Table 3. We ran GIZA++ for four iterations of Model 4 and used the "refined" heuristic (line 1). We ran the baseline semi-supervised system for two iterations (line 2), and in contrast with (Fraser and Marcu, 2006b) we found that the best symmetrization heuristic for this system was "union", which is most likely due to our use of fully linked alignments which was discussed at the end of Section 3. We observe that LEAF unsupervised (line 3) is competitive with GIZA++ (line 1), and is in fact competitive with the baseline semi-supervised result (line 2). We ran the LEAF semi-supervised system for two iterations (line 4). The best result is the LEAF semi-supervised system, with a gain of 1.8 F-Measure over the LEAF unsupervised system.

For French/English translation we use a state of the art phrase-based MT system similar to (Och and Ney, 2004; Koehn et al., 2003). The translation test data is described in Table 2. We use two trigram language models, one built using the English portion of the training data and the other built using additional English news data. The BLEU scores reported in this work are calculated using lowercased and tokenized data. For semi-supervised LEAF the gain of 0.46 BLEU over the semi-supervised baseline is not statistically significant (a gain of 0.78 BLEU would be required), but LEAF semi-supervised compared with GIZA++ is significant, with a gain of 1.23 BLEU. We note that this shows a large gain in trans-

[2] Unsupervised LEAF is equivalent to using the log-linear model and setting $\lambda_m = 1$ for $m = 1$ to 10 and $m = 16$ to 25, while setting $\lambda_m = 0$ for other values of m.

		Arabic/English		French/English	
		A	E	F	E
Training	Sents	6,609,162		2,842,184	
	Words	147,165,003	168,301,299	75,794,254	67,366,819
	Vocab	642,518	352,357	149,568	114,907
	Singletons	256,778	158,544	60,651	47,765
Align Discr.	Sents	1,000		110	
	Words	26,882	37,635	1,888	1,726
	Links	39,931		2,292	
Align Test	Sents	83		110	
	Words	1,510	2,030	1,899	1,716

lation quality over that obtained using GIZA++ because BLEU is calculated using only a single reference for the French/English task.

Results for the Arabic/English data set are also shown in Table 3. We used a large gold standard word alignment set available from the LDC. We ran GIZA++ for four iterations of Model 4 and used the "union" heuristic. We compare GIZA++ (line 1) with one iteration of the unsupervised LEAF model (line 2). The unsupervised LEAF system is worse than four iterations of GIZA++ Model 4. We believe that the features in LEAF are too high dimensional to use for the Arabic/English task without the backoffs available in the semi-supervised models. The baseline semi-supervised system (line 3) was run for three iterations and the resulting alignments were combined with the "union" heuristic. We ran the LEAF semi-supervised system for two iterations. The best result is the LEAF semi-supervised system (line 4), with a gain of 5.4 F-Measure over the baseline semi-supervised system.

For Arabic/English translation we train a state of the art hierarchical model similar to (Chiang, 2005) using our Viterbi alignments. The translation test data used is described in Table 2. We use two trigram language models, one built using the English portion of the training data and the other built using additional English news data. The test set is from the NIST 2005 translation task. LEAF had the best performance scoring 1.43 BLEU better than the baseline semi-supervised system, which is statistically significant.

5 Previous Work

The LEAF model is inspired by the literature on generative modeling for statistical word alignment and particularly by Model 4 (Brown et al., 1993). Much of the additional work on generative modeling of 1-to-N word alignments is based on the HMM model (Vogel et al., 1996). (Toutanova et al., 2002) and (Lopez and Resnik, 2005) presented a variety of refinements of the HMM model particularly effective for low data conditions. (Deng and Byrne, 2005) described work on extending the HMM model using a bigram formulation to generate 1-to-N alignment structure. The common thread connecting these works is their reliance on the 1-to-N approximation, while we have defined a generative model which does not require use of this approximation, at the cost of having to rely on local search.

There has also been work on generative models for other alignment structures. (Wang and Waibel, 1998) introduced a generative story based on extension of the generative story of Model 4. The alignment structure modeled was "consecutive M to non-consecutive N". (Marcu and Wong, 2002) defined the Joint model, which modeled consecutive word M-to-N alignments. (Matusov et al., 2004) presented a model capable of modeling 1-to-N and M-to-1 alignments (but not arbitrary M-to-N alignments) which was bootstrapped from Model 4. LEAF directly models non-consecutive M-to-N alignments.

One important aspect of LEAF is its symmetry. (Och and Ney, 2003) invented heuristic symmetriza-

Table 3: Experimental Results

tion of the output of a 1-to-N model and a M-to-1 model resulting in a M-to-N alignment, this was extended in (Koehn et al., 2003). We have used insights from these works to help determine the structure of our generative model. (Zens et al., 2004) introduced a model featuring a symmetrized lexicon. (Liang et al., 2006) showed how to train two HMM models, a 1-to-N model and a M-to-1 model, to agree in predicting all of the links generated, resulting in a 1-to-1 alignment with occasional rare 1-to-N or M-to-1 links. We improve on these works by choosing a new structure for our generative model, the head word link structure, which is both symmetric and a robust structure for modeling of non-consecutive M-to-N alignments.

In designing LEAF, we were also inspired by dependency-based alignment models (Wu, 1997; Alshawi et al., 2000; Yamada and Knight, 2001; Cherry and Lin, 2003; Zhang and Gildea, 2004). In contrast with their approaches, we have a very flat, one-level notion of dependency, which is bilingually motivated and learned automatically from the parallel corpus. This idea of dependency has some similarity with hierarchical SMT models such as (Chiang, 2005).

The discriminative component of our work is based on a plethora of recent literature. This literature generally views the discriminative modeling problem as a supervised problem involving the combination of heuristically derived feature functions. These feature functions generally include the prediction of some type of generative model, such as the HMM model or Model 4. A discriminatively trained 1-to-N model with feature functions specifically designed for Arabic was presented in (Ittycheriah and Roukos, 2005). (Lacoste-Julien et al., 2006) created a discriminative model able to model 1-to-1, 1-to-2 and 2-to-1 alignments for which the best results were obtained using features based on symmetric HMMs trained to agree, (Liang et al., 2006), and intersected Model 4. (Ayan and Dorr, 2006) defined a discriminative model which learns how to combine the predictions of several alignment algorithms. The experiments performed included Model 4 and the HMM extensions of (Lopez and Resnik, 2005). (Moore et al., 2006) introduced a discriminative model of 1-to-N and M-to-1 alignments, and similarly to (Lacoste-Julien et al., 2006) the best results were obtained using HMMs trained to agree and intersected Model 4. LEAF is not bound by the structural restrictions present either directly in these models, or in the features derived from the generative models used. We also iterate the generative/discriminative process, which allows the discriminative predictions to influence the generative model.

Our work is most similar to work using discriminative log-linear models for alignment, which is similar to discriminative log-linear models used for the SMT decoding (translation) problem (Och and Ney, 2002; Och, 2003). (Liu et al., 2005) presented a log-linear model combining IBM Model 3 trained in both directions with heuristic features which resulted in a 1-to-1 alignment. (Fraser and Marcu, 2006b) described symmetrized training of a 1-to-N log-linear model and a M-to-1 log-linear model. These models took advantage of features derived from both training directions, similar to the symmetrized lexicons of (Zens et al., 2004), including features derived from the HMM model and Model 4. However, despite the symmetric lexicons, these models were only able to optimize the performance of the 1-to-N model and the M-to-1 model separately, and the predictions of the two models required combination with symmetrization heuristics. We have overcome the limitations of that work by defining new feature functions, based on the LEAF generative model, which score non-consecutive M-to-N alignments so that the final performance criterion can be optimized directly.

6 Conclusion

We have found a new structure over which we can robustly predict which directly models translational correspondence commensurate with how it is used in hierarchical SMT systems. Our new generative model, LEAF, is able to model alignments which consist of M-to-N non-consecutive translational correspondences. Unsupervised LEAF is comparable with a strong baseline. When coupled with a discriminative training procedure, the model leads to increases between 3 and 9 F-score points in alignment accuracy and 1.2 and 2.8 BLEU points in translation accuracy over strong French/English and Arabic/English baselines.

Abstract

We show for the first time that incorporating the predictions of a word sense disambiguation system within a typical phrase-based statistical machine translation (SMT) model consistently improves translation quality across *all* three different IWSLT Chinese-English test sets, as well as producing statistically significant improvements on the larger NIST Chinese-English MT task—and moreover *never* hurts performance on any test set, according not only to BLEU but to *all eight* most commonly used automatic evaluation metrics. Recent work has challenged the assumption that word sense disambiguation (WSD) systems are useful for SMT. Yet SMT translation quality still obviously suffers from inaccurate lexical choice. In this paper, we address this problem by investigating a new strategy for integrating WSD into an SMT system, that performs *fully phrasal multi-word* disambiguation. Instead of directly incorporating a Senseval-style WSD system, we redefine the WSD task to match the exact same phrasal translation disambiguation task faced by phrase-based SMT systems. Our results provide the first known empirical evidence that lexical semantics are indeed useful for SMT, despite claims to the contrary.

1 Introduction

Common assumptions about the role and usefulness of word sense disambiguation (WSD) models in full-scale statistical machine translation (SMT) systems have recently been challenged.

On the one hand, in previous work (Carpuat and Wu, 2005b) we obtained disappointing results when using the predictions of a Senseval WSD system in conjunction with a standard word-based SMT system: we reported slightly lower BLEU scores despite trying to incorporate WSD using a number of apparently sensible methods. These results cast doubt on the assumption that sophisticated dedicated WSD systems that were developed independently from any particular NLP application can easily be integrated into a SMT system so as to improve translation quality through stronger models of context and rich linguistic information. Rather, it has been argued, SMT systems have managed to achieve significant improvements in translation quality without directly addressing translation disambiguation as a WSD task. Instead, translation disambiguation decisions are made indirectly, typically using only word surface forms and very local contextual information, forgoing the much richer linguistic information that WSD systems typically take advantage of.

On the other hand, error analysis reveals that the performance of SMT systems still suffers from inaccurate lexical choice. In subsequent empirical studies, we have shown that SMT systems perform much worse than dedicated WSD models, both supervised

and unsupervised, on a Senseval WSD task (Carpuat and Wu, 2005a), and therefore suggest that WSD should have a role to play in state-of-the-art SMT systems. In addition to the Senseval shared tasks, which have provided standard sense inventories and data sets, WSD research has also turned increasingly to designing specific models for a particular application. For instance, Vickrey *et al.* (2005) and Specia (2006) proposed WSD systems designed for French to English, and Portuguese to English translation respectively, and present a more optimistic outlook for the use of WSD in MT, although these WSD systems have not yet been integrated nor evaluated in full-scale machine translation systems.

Taken together, these seemingly contradictory results suggest that improving SMT lexical choice accuracy remains a key challenge to improve current SMT quality, and that it is still unclear what is the most appropriate integration framework for the WSD models in SMT.

In this paper, we present first results with a new architecture that integrates a state-of-the-art WSD model into phrase-based SMT so as to perform *multi-word phrasal* lexical disambiguation, and show that this new WSD approach not only produces gains across *all* available Chinese-English IWSLT06 test sets for all eight commonly used automated MT evaluation metrics, but also produces statistically significant gains on the much larger NIST Chinese-English task. The main difference between this approach and several of our earlier approaches as described in Carpuat and Wu (2005b) and subsequently Carpuat *et al.* (2006) lies in the fact that we focus on repurposing the WSD system for multi-word phrase-based SMT. Rather than using a generic Senseval WSD model as we did in Carpuat and Wu (2005b), here both the WSD training and the WSD predictions are integrated into the phrase-based SMT framework. Furthermore, rather than using a single word based WSD approach to augment a phrase-based SMT model as we did in Carpuat *et al.* (2006) to improve BLEU and NIST scores, here the WSD training and predictions operate on full multi-word phrasal units, resulting in significantly more reliable and consistent gains as evaluted by many other translation accuracy metrics as well. Specifically:

- Instead of using a Senseval system, we redefine the WSD task to be exactly the same as lexical choice task faced by the multi-word phrasal translation disambiguation task faced by the phrase-based SMT system.

- Instead of using predefined senses drawn from manually constructed sense inventories such as HowNet (Dong, 1998), our WSD for SMT system directly disambiguates between all phrasal translation candidates seen during SMT training.

- Instead of learning from manually annotated training data, our WSD system is trained on the same corpora as the SMT system.

However, despite these adaptations to the SMT task, the core sense disambiguation task remains pure WSD:

- The rich context features are typical of WSD and almost never used in SMT.

- The dynamic integration of context-sensitive translation probabilities is not typical of SMT.

- Although it is embedded in a real SMT system, the WSD task is exactly the same as in recent and coming Senseval Multilingual Lexical Sample tasks (e.g., Chklovski *et al.* (2004)), where sense inventories represent the semantic distinctions made by another language.

We begin by presenting the WSD module and the SMT integration technique. We then show that incorporating it into a standard phrase-based SMT baseline system *consistently improves translation quality* across all three different test sets from the Chinese-English IWSLT text translation evaluation, as well as on the larger NIST Chinese-English translation task. Depending on the metric, the individual gains are sometimes modest, but remarkably, incorporating WSD *never* hurts, and helps enough to always make it a worthwile additional component in an SMT system. Finally, we analyze the reasons for the improvement.

2 Problems in context-sensitive lexical choice for SMT

To the best of our knowledge, there has been no previous attempt at integrating a state-of-the-art WSD system for fully phrasal multi-word lexical choice into phrase-based SMT, with evaluation of the resulting system on a translation task. While there are many evaluations of WSD quality, in particular the Senseval series of shared tasks (Kilgarriff and Rosenzweig (1999), Kilgarriff (2001), Mihalcea *et al.* (2004)), very little work has been done to address the actual integration of WSD in realistic SMT applications.

To fully integrate WSD into phrase-based SMT, it is necessary to perform lexical disambiguation on *multi-word phrasal* lexical units; in contrast, the model reported in Cabezas and Resnik (2005) can only perform lexical disambiguation on *single words*. Like the model proposed in this paper, Cabezas and Resnik attempted to integrate phrase-based WSD models into decoding. However, although they reported that incorporating these predictions via the Pharaoh XML markup scheme yielded a small improvement in BLEU score over a Pharaoh baseline on a single Spanish-English translation data set, we have determined empirically that applying their single-word based model to several Chinese-English datasets does *not* yield systematic improvements on most MT evaluation metrics (Carpuat and Wu, 2007). The single-word model has the disadvantage of forcing the decoder to choose between the baseline phrasal translation probabilities versus the WSD model predictions for single words. In addition, the single-word model does not generalize to WSD for phrasal lexical choice, as overlapping spans cannot be specified with the XML markup scheme. Providing WSD predictions for phrases would require committing to a phrase segmentation of the input sentence before decoding, which is likely to hurt translation quality.

It is also necessary to focus directly on translation accuracy rather than other measures such as alignment error rate, which may not actually lead to improved translation quality; in contrast, for example, Garcia-Varea *et al.* (2001) and Garcia-Varea *et al.* (2002) show improved alignment error rate with a maximum entropy based context-dependent lexical choice model, but not improved translation accuracy. In contrast, our evaluation in this paper is conducted on the actual decoding task, rather than intermediate tasks such as word alignment. Moreover, in the present work, *all* commonly available automated MT evaluation metrics are used, rather than only BLEU score, so as to maintain a more balanced perspective.

Another problem in the context-sensitive lexical choice in SMT models of Garcia Varea *et al.* is that their feature set is insufficiently rich to make much better predictions than the SMT model itself. In contrast, our WSD-based lexical choice models are designed to directly model the lexical choice in the actual translation direction, and take full advantage of not residing strictly within the Bayesian source-channel model in order to benefit from the much richer Senseval-style feature set this facilitates.

Garcia Varea *et al.* found that the best results are obtained when the training of the context-dependent translation model is fully incorporated with the EM training of the SMT system. As described below, the training of our new WSD model, though not incorporated within the EM training, is also far more closely tied to the SMT model than is the case with traditional standalone WSD models.

In contrast with Brown *et al.* (1991), our approach incorporates the predictions of state-of-the-art WSD models that use rich contextual features for any phrase in the input vocabulary. In Brown *et al.*'s early study of WSD impact on SMT performance, the authors reported improved translation quality on a French to English task, by choosing an English translation for a French word based on the single contextual feature which is reliably discriminative. However, this was a pilot study, which is limited to words with exactly two translation candidates, and it is not clear that the conclusions would generalize to more recent SMT architectures.

3 Problems in translation-oriented WSD

The close relationship between WSD and SMT has been emphasized since the emergence of WSD as an independent task. However, most of previous research has focused on using multilingual resources typically used in SMT systems to improve WSD accuracy, e.g., Dagan and Itai (1994), Li and Li (2002), Diab (2004). In contrast, this paper focuses on the converse goal of using WSD models to improve actual translation quality.

Recently, several researchers have focused on designing WSD systems for the specific purpose of translation. Vickrey *et al.* (2005) train a logistic regression WSD model on data extracted from automatically word aligned parallel corpora, but evaluate on a blank filling task, which is essentially an evaluation of WSD accuracy. Specia (2006) describes an inductive logic programming-based WSD system, which was specifically designed for the purpose of Portuguese to English translation, but this system was also only evaluated on WSD accuracy, and not integrated in a full-scale machine translation system.

Ng *et al.* (2003) show that it is possible to use automatically word aligned parallel corpora to train accurate supervised WSD models. The purpose of the study was to lower the annotation cost for supervised WSD, as suggested earlier by Resnik and Yarowsky (1999). However this result is also encouraging for the integration of WSD in SMT, since it suggests that accurate WSD can be achieved using training data of the kind needed for SMT.

4 Building WSD models for phrase-based SMT

4.1 WSD models for every phrase in the input vocabulary

Just like for the baseline phrase translation model, WSD models are defined for every phrase in the input vocabulary. Lexical choice in SMT is naturally framed as a WSD problem, so the first step of integration consists of defining a WSD model for every phrase in the SMT input vocabulary.

This differs from traditional WSD tasks, where the WSD target is a single content word. Senseval for instance has either lexical sample or all word tasks. The target words for both categories of Senseval WSD tasks are typically only content words—primarily nouns, verbs, and adjectives—while in the context of SMT, we need to translate entire sentences, and therefore have a WSD model not only for every word in the input sentences, regardless of their POS tag, but for every phrase, including tokens such as articles, prepositions and even punctuation. Further empirical studies have suggested that including WSD predictions for those longer phrases is a key factor to help the decoder produce better translations (Carpuat and Wu, 2007).

4.2 WSD uses the same sense definitions as the SMT system

Instead of using pre-defined sense inventories, the WSD models disambiguate between the SMT translation candidates. In order to closely integrate WSD predictions into the SMT system, we need to formulate WSD models so that they produce features that can directly be used in translation decisions taken by the SMT system. It is therefore necessary for the WSD and SMT systems to consider exactly the same translation candidates for a given word in the input language.

Assuming a standard phrase-based SMT system (e.g., Koehn *et al.* (2003)), WSD senses are thus either words or phrases, as learned in the SMT phrasal translation lexicon. Those "sense" candidates are very different from those typically used even in dedicated WSD tasks, even in the multilingual Senseval tasks. Each candidate is a phrase that is not necessarily a syntactic noun or verb phrase as in manually compiled dictionaries. It is quite possible that distinct "senses" in our WSD for SMT system could be considered synonyms in a traditional WSD framework, especially in monolingual WSD.

In addition to the consistency requirements for integration, this requirement is also motivated by empirical studies, which show that predefined translations derived from sense distinctions defined in monolingual ontologies do not match translation distinction made by human translators (Specia *et al.*, 2006).

4.3 WSD uses the same training data as the SMT system

WSD training does not require any other resources than SMT training, nor any manual sense annotation. We employ supervised WSD systems, since Senseval results have amply demonstrated that supervised models significantly outperform unsupervised approaches (see for instance the English lexical sample tasks results described by Mihalcea *et al.* (2004)).

Training examples are annotated using the phrase alignments learned during SMT training. Every input language phrase is sense-tagged with its aligned output language phrase in the parallel corpus. The phrase alignment method used to extract the WSD training data therefore depends on the one used by the SMT system. This presents the advantage of training WSD and SMT models on exactly the same data, thus eliminating domain mismatches between Senseval data and parallel corpora. But most importantly, this allows WSD training data to be generated entirely automatically, since the parallel corpus is automatically phrase-aligned in order to learn the SMT phrase bilexicon.

4.4 The WSD system

The word sense disambiguation subsystem is modeled after the best performing WSD system in the Chinese lexical sample task at Senseval-3 (Carpuat *et al.*, 2004).

The features employed are typical of WSD and are therefore far richer than those used in most SMT systems. The feature set consists of position-sensitive, syntactic, and local collocational features, since these features yielded the best results when combined in a naïve Bayes model on several Senseval-2 lexical sample tasks (Yarowsky and Florian, 2002). These features scale easily to the bigger vocabulary and sense candidates to be considered in a SMT task.

The Senseval system consists of an ensemble of four combined WSD models:

The first model is a naïve Bayes model, since Yarowsky and Florian (2002) found this model to be the most accurate classifier in a comparative study on a subset of Senseval-2 English lexical sample data.

The second model is a maximum entropy model (Jaynes, 1978), since Klein and Manning (Klein and Manning, 2002) found that this model yielded higher accuracy than naïve Bayes in a subsequent comparison of WSD performance.

The third model is a boosting model (Freund and Schapire, 1997), since boosting has consistently turned in very competitive scores on related tasks such as named entity classification. We also use the Adaboost.MH algorithm.

The fourth model is a Kernel PCA-based model (Wu *et al.*, 2004). Kernel Principal Component Analysis or KPCA is a nonlinear kernel method for extracting nonlinear principal components from vector sets where, conceptually, the n-dimensional input vectors are nonlinearly mapped from their original space R^n to a high-dimensional feature space F where linear PCA is performed, yielding a transform by which the input vectors can be mapped nonlinearly to a new set of vectors (Schölkopf *et al.*, 1998). WSD can be performed by a Nearest Neighbor Classifier in the high-dimensional KPCA feature space.

All these classifiers have the ability to handle large numbers of sparse features, many of which may be irrelevant. Moreover, the maximum entropy and boosting models are known to be well suited to handling features that are highly interdependent.

4.5 Integrating WSD predictions in phrase-based SMT architectures

It is non-trivial to incorporate WSD into an existing phrase-based architecture such as Pharaoh (Koehn, 2004), since the decoder is not set up to easily accept multiple translation probabilities that are dynamically computed in context-sensitive fashion.

For every *phrase* in a given SMT input sentence, the WSD probabilities can be used as additional feature in a loglinear translation model, in combination with typical context-independent SMT bilexicon probabilities.

We overcome this obstacle by devising a calling architecture that reinitializes the decoder with dynamically generated lexicons on a per-sentence basis.

Unlike a n-best reranking approach, which is limited by the lexical choices made by the decoder using only the baseline context-independent translation probabilities, our method allows the system to make full use of WSD information for all competing phrases at all decoding stages.

5 Experimental setup

The evaluation is conducted on two standard Chinese to English translation tasks. We follow standard machine translation evaluation procedure using automatic evaluation metrics. Since our goal is to evaluate translation quality, we use standard MT evaluation methodology and do not evaluate the accuracy of the WSD model independently.

Table 1: Evaluation results on the IWSLT06 dataset: integrating the WSD translation predictions improves BLEU, NIST, METEOR, WER, PER, CDER and TER across all 3 different available test sets.

Test Set	**Exper.**	**BLEU**	**NIST**	**METEOR**	**METEOR (no syn)**	**TER**	**WER**	**PER**	**CDER**
Test 1	SMT	42.21	7.888	65.40	63.24	40.45	45.58	37.80	40.09
	SMT+WSD	**42.38**	**7.902**	**65.73**	**63.64**	**39.98**	**45.30**	**37.60**	**39.91**

5.1 Data set

Preliminary experiments are conducted using training and evaluation data drawn from the multilingual BTEC corpus, which contains sentences used in conversations in the travel domain, and their translations in several languages. A subset of this data was made available for the IWSLT06 evaluation campaign (Paul, 2006); the training set consists of 40000 sentence pairs, and each test set contains around 500 sentences. We used only the pure text data, and not the speech transcriptions, so that speech-specific issues would not interfere with our primary goal of understanding the effect of integrating WSD in a full-scale phrase-based model.

A larger scale evaluation is conducted on the standard NIST Chinese-English test set (MT-04), which contains 1788 sentences drawn from newswire corpora, and therefore of a much wider domain than the IWSLT data set. The training set consists of about 1 million sentence pairs in the news domain.

Basic preprocessing was applied to the corpus. The English side was simply tokenized and case-normalized. The Chinese side was word segmented using the LDC segmenter.

5.2 Baseline SMT system

Since our focus is not on a specific SMT architecture, we use the off-the-shelf phrase-based decoder Pharaoh (Koehn, 2004) trained on the IWSLT training set. Pharaoh implements a beam search decoder for phrase-based statistical models, and presents the advantages of being freely available and widely used.

The phrase bilexicon is derived from the intersection of bidirectional IBM Model 4 alignments, obtained with GIZA++ (Och and Ney, 2003), augmented to improve recall using the grow-diag-final heuristic. The language model is trained on the English side of the corpus using the SRI language modeling toolkit (Stolcke, 2002).

The loglinear model weights are learned using Chiang's implementation of the maximum BLEU training algorithm (Och, 2003), both for the baseline, and the WSD-augmented system. Due to time constraints, this optimization was only conducted on the IWSLT task. The weights used in the WSD-augmented NIST model are based on the best IWSLT model. Given that the two tasks are quite different, we expect further improvements on the WSD-augmented system after running maximum BLEU optimization for the NIST task.

6 Results and discussion

Using WSD predictions in SMT yields better translation quality on *all* test sets, as measured by *all eight* commonly used automatic evaluation metrics.

Table 3: Translation examples with and without WSD for SMT, drawn from IWSLT data sets.

Input	请 转 乘 中央 线 。
Ref.	Please transfer to the Chuo train line.
SMT	Please turn to the Central Line.
SMT+WSD	Please transfer to Central Line.
Input	车票 在 车上 买 吗 ？
Ref.	Do I pay on the bus?
SMT	Please get on the bus?
SMT+WSD	I buy a ticket on the bus?
Input	需要 预订 吗 ？
Ref.	Do I need a reservation?
SMT	I need a reservation?
SMT+WSD	Do I need a reservation?
Input	我 想 再 确认 一下 这 张 票 的 预订 。
Ref.	I want to reconfirm this ticket.
SMT	I would like to reconfirm a flight for this ticket.
SMT+WSD	I would like to reconfirm my reservation for this ticket.
Input	步行 可以 到 那里 吗 ？
Ref.	Can I get there on foot?
SMT	Is there on foot?
SMT+WSD	Can I get there on foot?
Input	我 有 另外 一个 约会 ， 所以 请 快点 。
Ref.	I have another appointment, so please hurry.
SMT	I have an appointment for a, so please hurry.
SMT+WSD	I have another appointment, so please hurry.
Input	对不起 。 你 能 告诉 我 到 百老汇 的 路 吗 ？
Ref.	Excuse me. Could you tell me the way to Broadway?
SMT	Could you tell me the way to Broadway? I am sorry.
SMT+WSD	Excuse me, could you tell me the way to Broadway?
Input	对不起 ， 我 想 开 一个 账 户 。
Ref.	Excuse me, I want to open an account.
SMT	Excuse me, I would like to have an account.
SMT+WSD	Excuse me, I would like to open an account.

The results are shown in Table 1 for IWSLT and Table 2 for the NIST task. Paired bootstrap resampling shows that the improvements on the NIST test set are statistically significant at the 95% level.

Remarkably, integrating WSD predictions helps all the very different metrics. In addition to the widely used BLEU (Papineni *et al.*, 2002) and NIST (Doddington, 2002) scores, we also evaluate translation quality with the recently proposed Meteor (Banerjee and Lavie, 2005) and four edit-distance style metrics, Word Error Rate (WER), Position-independent word Error Rate (PER) (Tillmann *et al.*, 1997), CDER, which allows block reordering (Leusch *et al.*, 2006), and Translation Edit Rate (TER) (Snover *et al.*, 2006). Note that we report Meteor scores computed both with and without using WordNet synonyms to match translation candidates and references, showing that the improvement is not due to context-independent synonym matches at evaluation time.

Comparison of the 1-Best decoder output with and without the WSD feature shows that the sentences differ by one or more token respectively for 25.49%, 30.40% and 29.25% of IWSLT test sets 1,

Table 4: Translation examples with and without WSD for SMT, drawn from the NIST test set.

Input	没有 任何 议员 投票 反对 他 。
SMT	Without any congressmen voted against him.
SMT+WSD	No congressmen voted against him.
Input	俄 在 车臣 实行 的 政策 以及 对 独 联 体 邻国 的 态度 更 是 令 美国 担忧 。

SMT+WSD	In order to prevent terrorist activities Los Angeles, the police to an unprecedented tight security measures.

2 and 3, and 95.74% of the NIST test set.

Tables 3 and 4 show examples of translations drawn from the IWSLT and NIST test sets respectively.

A more detailed analysis reveals WSD predictions give better rankings and are more discriminative than baseline translation probabilities, which helps the final translation in three different ways.

- The rich context features help rank the correct translation first with WSD while it is ranked lower according to baseline translation probability scores .

- Even when WSD and baseline translation probabilities agree on the top translation candidate, the stronger WSD scores help override wrong language model predictions.

- The strong WSD scores for phrases help the decoder pick longer phrase translations, while using baseline translation probabilities often translate those phrases in smaller chunks that include a frequent (and incorrect) translation candidate.

For instance, the top 4 Chinese sentences in Table 4, are better translated by the WSD-augmented system because the WSD scores help the decoder to choose longer phrases. In the first example, the phrase “没有 任何” is correctly translated as a whole as “No” by the WSD-augmented system, while the baseline translates each word separately yielding an incorrect translation. In the following three examples, the WSD system encourages the decoder to translate the long phrases “更 是 令 美国 担忧”, “美国 的 人权 状况”, and “祈求 日本 的 和平 与 繁荣” as single units, while the baseline introduces errors by breaking them down into shorter phrases.

The last sentence in the table shows an example where the WSD predictions do not help the baseline system. The translation quality is actually much worse, since the verb “采取” is incorrectly translated as “to”, despite the fact that the top candidate predicted by the WSD system alone is the much better translation “has taken”, but with a relatively low probability of 0.509.

7 Conclusion

We have shown for the first time that integrating multi-word phrasal WSD models into phrase-based

SMT consistently helps on all commonly available automated translation quality evaluation metrics on all three different test sets from the Chinese-English IWSLT06 text translation task, and yields statistically significant gains on the larger NIST Chinese-English task. It is important to note that the WSD models *never* hurt translation quality, and always yield individual gains of a level that makes their integration always worthwile.

We have proposed to consistently integrate WSD models both during training, where sense definitions and sense-annotated data are automatically extracted from the word-aligned parallel corpora from SMT training, and during testing, where the phrasal WSD probabilities are used by the SMT system just like all the other lexical choice features.

Context features are derived from state-of-the-art WSD models, and the evaluation is conducted on the actual translation task, rather than intermediate tasks such as word alignment.

It is to be emphasized that this approach does not merely consist of adding a source sentence feature in the log linear model for translation. On the contrary, it remains a real WSD task, defined just as in the Senseval Multilingual Lexical Sample tasks (e.g., Chklovski *et al.* (2004)). Our model makes use of typical WSD features that are almost never used in SMT systems, and requires a dynamically created translation lexicon on a per-sentence basis.

To our knowledge this constitues the first attempt at fully integrating state-of-the-art WSD with conventional phrase-based SMT. Unlike previous approaches, the WSD targets are not only single words, but *multi-word phrases*, just as in the SMT system. This means that WSD senses are unusually predicted not only for a limited set of single words or very short phrases, but for all phrases of arbitrarily length that are in the SMT translation lexicon. The single word approach, as we reported in Carpuat *et al.* (2006), improved BLEU and NIST scores for phrase-based SMT, but subsequent detailed empirical studies we have performed since then suggest that single word WSD approaches are less successful when evaluated under all other MT metrics (Carpuat and Wu, 2007). Thus, fully phrasal WSD predictions for longer phrases, as reported in this paper, are particularly important to improve translation quality.

The results reported in this paper cast new light on the WSD vs. SMT debate, suggesting that a close integration of WSD and SMT decisions should be incorporated in a SMT model that successfully uses WSD predictions. Our objective here is to demonstrate that this technique works for the widest possible class of models, so we have chosen as the baseline the most widely used phrase-based SMT model. Our positive results suggest that our experiments could be tried on other current statistical MT models, especially the growing family of tree-structured SMT models employing stochastic transduction grammars of various sorts (Wu and Chiang, 2007). For instance, incorporating WSD predictions into an MT decoder based on inversion transduction grammars (Wu, 1997)—such as the Bracketing ITG based models of Wu (1996), Zens *et al.* (2004), or Cherry and Lin (2007)—would present an intriguing comparison with the present work. It would also be interesting to assess whether a more grammatically structured statistical MT model that is less reliant on an n-gram language model, such as the syntactic ITG based "grammatical channel" translation model of (Wu and Wong, 1998), could make more effective use of WSD predictions.

Large Margin Synchronous Generation and its Application to Sentence Compression

Trevor Cohn and **Mirella Lapata**

Abstract

This paper presents a tree-to-tree transduction method for text rewriting. Our model is based on synchronous tree substitution grammar, a formalism that allows local distortion of the tree topology and can thus naturally capture structural mismatches. We describe an algorithm for decoding in this framework and show how the model can be trained discriminatively within a large margin framework. Experimental results on sentence compression bring significant improvements over a state-of-the-art model.

1 Introduction

Recent years have witnessed increasing interest in text-to-text generation methods for many natural language processing applications ranging from text summarisation to question answering and machine translation. At the heart of these methods lies the ability to perform rewriting operations according to a set of prespecified constraints. For example, text simplification identifies which phrases or sentences in a document will pose reading difficulty for a given user and substitutes them with simpler alternatives (Carroll et al., 1999). Sentence compression produces a summary of a single sentence that retains the most important information while remaining grammatical (Jing, 2000).

Ideally, we would like a text-to-text rewriting system that is not application specific. Given a parallel corpus of training examples, we should be able to learn rewrite rules and how to combine them in order to generate new text. A great deal of previous work has focused on the rule induction problem (Barzilay and McKeown, 2001; Pang et al., 2003; Lin and Pantel, 2001; Shinyama et al., 2002), whereas relatively little emphasis has been placed on the actual generation task (Quirk et al., 2004). A notable exception is sentence compression for which end-to-end rewriting systems are commonly developed (Knight and Marcu, 2002; Turner and Charniak, 2005; Galley and McKeown, 2007; Riezler et al., 2003; McDonald, 2006). The appeal of this task lies in its simplified formulation as a single rewrite operation, namely word deletion (Knight and Marcu, 2002).

Solutions to the compression task have been cast mostly in a supervised learning setting (but see Clarke and Lapata (2006a), Hori and Furui (2004), and Turner and Charniak (2005) for unsupervised methods). Rewrite rules are learnt from a parsed parallel corpus and subsequently used to find the best compression from the set of all possible compressions for a given sentence. A common assumption is that the tree structures representing long sentences and their compressions are *isomorphic*. Consequently, the models are not generally applicable to other text rewriting problems since they cannot readily handle structural mismatches and more complex rewriting operations such as substitutions or insertions. A related issue is that the tree structure of the compressed sentences is often poor; most algorithms delete words or constituents without paying too much attention to the structure of the compressed sentence. However, without an explicit generation mechanism that allows tree transformations, there is no guarantee that the compressions will have well-formed syntactic structures. And it will not be easy to process them for subsequent generation or analysis tasks.

In this paper we present a text-to-text rewriting

Proceedings of the 2007 Joint Conference on Empirical Methods in Natural Language Processing and Computational Natural Language Learning, pp. 73–82, Prague, June 2007. ©2007 Association for Computational Linguistics

model that scales to *non-isomorphic* cases and can thus naturally account for structural and lexical divergences. Our approach is inspired by *synchronous tree substitution grammar* (STSG, Eisner (2003)) a formalism that allows local distortion of the tree topology. We show how such a grammar can be induced from a parallel corpus and propose a large margin model for the rewriting task which can be viewed as a weighted tree-to-tree transducer. Our learning framework makes use of the algorithm put forward by Tsochantaridis et al. (2005) which efficiently learns a prediction function to minimise a given loss function. Experiments on sentence compression show significant improvements over the state-of-the-art. Beyond sentence compression and related text-to-text generation problems (*e.g.,* paraphrasing), our model is generally applicable to tasks involving structural mapping. Examples include machine translation (Eisner, 2003) or semantic parsing (Zettlemoyer and Collins, 2005).

2 Related Work

Knight and Marcu (2002) proposed a noisy-channel formulation of sentence compression based on synchronous context-free grammar (SCFG). The latter is a generalisation of the context-free grammar (CFG) formalism to simultaneously produce strings in two languages. In the case of sentence compression, the grammar rules have two right hand sides, one corresponding to the *source* (long) sentence and the other to its *target* compression. The synchronous derivations are learnt from a parallel corpus and their probabilities are estimated generatively.

Given a long sentence, l, the aim is to find the corresponding compressed sentence, s, which maximises $P(s)P(l|s)$ (here $P(s)$ is the source model and $P(l|s)$ the channel model.) Modifications of this model are reported in Turner and Charniak (2005) and Galley and McKeown (2007) with improved results. The channel model is limited to tree deletion and does not allow any type of tree re-organisation.

Non-isomorphic tree structures are common when translating between languages. It is therefore not surprising that most previous work on tree rewriting falls within the realm of machine translation. Proposals include Eisner's (2003) synchronous tree substitution grammar (STSG), Melamed's (2004) multitext grammar, and Graehl and Knight's (2004) tree-to-tree transducers. Despite differences in formalism, all these approaches model the translation process using tree-based probabilistic transduction rules. The grammar induction process requires EM training which can be computationally expensive especially if all synchronous rules are considered.

Our work formulates sentence compression in the framework of STSG (Eisner, 2003). We propose a novel grammar induction algorithm that does not require EM training and is coupled with a separate large margin training process (Tsochantaridis et al., 2005) for weighting each rule. McDonald (2006) also presents a sentence compression model that uses a discriminative large margin algorithm. However, we differ in two important respects. First, our generation algorithm is more powerful, performing complex tree transformations, whereas McDonald only considers simple word deletion. Being tree-based, the generation algorithm is better able to preserve the grammaticality of the compressed output. Second, our model can be tuned to a wider range of loss functions (*e.g.,*tree-based measures).

3 Problem Formulation

We formulate sentence compression as an instance of the general problem of learning a mapping from input patterns $\mathbf{x} \in \mathcal{X}$ to discrete structured objects $\mathbf{y} \in \mathcal{Y}$. Our training sample consists of a parallel corpus of input (uncompressed) and output (compressed) pairs $(x_1, y_1) \ldots (x_n, y_n) \in \mathcal{X} \times \mathcal{Y}$ and our task is to predict a target labelled tree $\mathbf{y}$ from a source labelled tree $\mathbf{x}$. As we describe below, $\mathbf{y}$ is not precisely a target tree, but instead derivations which generate both the source and the target tree. We model the dependency between $\mathbf{x}$ and $\mathbf{y}$ as a weighted STSG. Grammar rules are of the form $\langle X, Y \rangle \rightarrow \langle \gamma, \alpha, \beta \rangle$ where γ and α are *elementary trees* composed of a mixture of terminal and non-terminals rooted with non-terminals X and Y respectively, and β is a set of variable correspondences between pairs of frontier non-terminals in γ and α. A grammar rule specifies that we can substitute the trees γ and α for corresponding X and Y nodes in the source and target trees respectively. For example, the rule:

$$\langle NP,\ NP \rangle \rightarrow \langle [DT_{\boxed{1}}\ ADJP\ NN_{\boxed{2}}]_{NP}, [DT_{\boxed{1}}\ NN_{\boxed{2}}]_{NP} \rangle$$

allows adjective phrases to be dropped from the source tree within an NP. The indices $_{\boxed{x}}$ are used to specify the variable correspondences, β.

Each grammar rule has a score from which the overall score of a compression $\mathbf{y}$ for sentence $\mathbf{x}$ can be derived. These scores are learnt discriminatively using the large margin technique proposed by Tsochantaridis et al. (2005). The synchronous rules are combined using a chart-based parsing algorithm (Eisner, 2003) to generate the derivation (i.e., compressed tree) with the highest score.

We begin by describing our STSG generation algorithm in Section 3.1. We next explain how a synchronous grammar is induced from a parallel corpus of original sentences and their compressions (Section 3.2) and give the details of our learning framework (Section 3.3).

3.1 Generation

Generation aims to find the best target tree for a given source tree using the transformations specified by the synchronous grammar. (We discuss how we obtain this grammar in the following section.)

$$\mathbf{y}^* = \max_{\mathbf{y} \in \mathcal{Y}} score(\mathbf{x}, \mathbf{y}; \mathbf{w}) \qquad (1)$$

where $\mathbf{y}$ ranges over all target derivations (and therefore trees), $\mathbf{w}$ is a parameter vector and $score(\cdot)$ is an objective function measuring the quality of the derivation. In common with many parsing methods, we encounter a problem with *spurious ambiguity*: i.e., there may be many *derivations* (sequences of rule applications) which produce the same target tree. Ideally we would sum up the scores over all these derivations, however for the sake of tractability we instead take the maximum score. This allows us to pose the maximisation problem over *derivations* rather than target trees.

The generation algorithm uses a dynamic program defined over the constituents in the source tree as shown in Figure 1 (see also Eisner (2003)). The algorithm makes the assumption that the scoring function decomposes with the derivation, such that a partial score can be evaluated at each step, i.e., $score(\mathbf{x}, \mathbf{y}; \mathbf{w}) = \sum_{r \in \mathbf{y}} score(r; \mathbf{w})$ where r are the rules used in the derivation. This method builds a *chart* of the best scoring partial derivation for each source subtree headed by a given target non-terminal. The inductive step is applied recursively bottom-up, and involves applying a grammar rule to a node in the source tree. Rules with substitution variables in their frontier are scored with reference to the chart for the matching nodes and target non-terminal categories. Once the process is complete, we can read the best score from the chart cell for the root node, and the best derivation can be constructed by traversing *back-pointers* also stored in the chart. This is illustrated in Figure 2 where the rule $\langle VP, VP \rangle \rightarrow \langle [[\text{is}_{AUX}\, ADJP_{\boxed{1}}]_{VP}\, CC\, VP]_{VP}, [\text{is}_{AUX}\, NP_{\boxed{1}}]_{VP} \rangle$ is applied to the top VP node. The score of the resulting tree would reference the chart to calculate the score for the best target tree at the $ADJP$ node with syntactic category NP.

```
for all nodes, $n$, in source tree (bottom-up) do
    for all rules, $r$ with left side matching node, $n_r = n$ do
        $s = score(r)$
        for all variables $v$ in $r$ do
            $score = score + chart[n_v, c_v]$
        end for
        update $chart[n, c_r]$ with score, $s$, if better than current
    end for
end for
$c_{best} = \text{argmax}_c\, chart[root, c]$
find best derivation using back-pointers from $(root, c_{best})$
```

Figure 1: Generation algorithm to find the best derivation. n_r and n_v are the source nodes indexed by the rule's source side (root and variable), while c_r and c_v are the non-terminal categories of the rule's target side (root and variable).

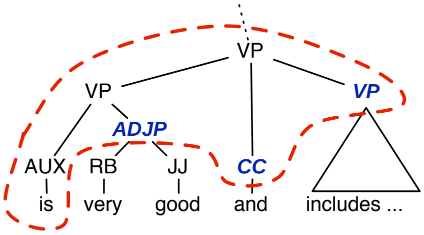

Figure 2: Example of a rule application during generation. The dashed area shows a matching rule for the VP node.

3.2 Grammar Induction

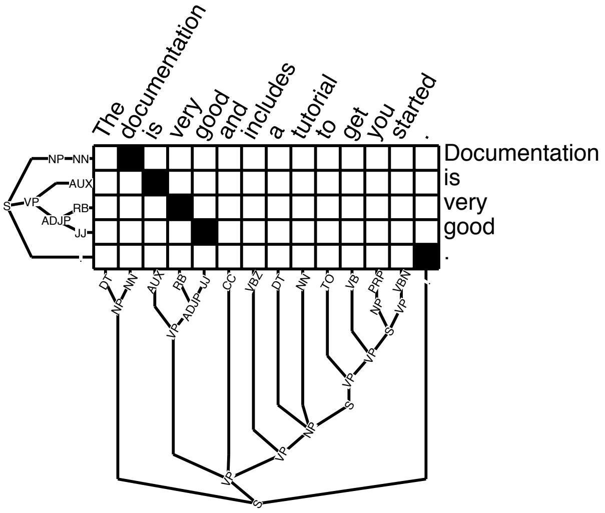
Our induction algorithm automatically finds grammar rules from a word-aligned parsed parallel corpus. The rules are pairs of *elementary trees* (i.e., tree fragments) whose leaf nodes are linked by the word alignments. These leaves can be either terminal or non-terminal symbols. Initially, the algorithm extracts tree pairs from word aligned text by choosing aligned constituents in the source and the target. These pairs are then generalised using subtrees which are also extracted, resulting in synchronous rules with variable nodes. The set of aligned tree pairs are extracted using the alignment template method (Och and Ney, 2004), constrained to syntactic constituent pairs:

$$\mathcal{C} = \{(n_S, n_T),\ (\exists(s,t) \in \mathcal{A} \wedge s \in Y(n_S) \wedge t \in Y(n_T)) \wedge \\ (\nexists(s,t) \in \mathcal{A} \wedge (s \in Y(n_S) \veebar t \in Y(n_T)))\}$$

where n_S and n_T are source and target tree nodes (subtrees), $\mathcal{A} = \{(s,t)\}$ is the set of word alignments (pairs of word-indices), $Y(\cdot)$ returns the yield span for a subtree and $\veebar$ is the exclusive-or operator.

The next step is to generalise the candidate pairs by replacing subtrees with variable nodes. We could fully trust the word alignments and adopt a strategy in which the rules are generalised as much as possible and thus include little lexicalisation. Figure 3 shows a simple sentence pair and the resulting synchronous rules according to this generalisation strategy. Alternatively, we could extract every possible rule by including unlexicalised rules, lexicalised rules and their combination. The downside here is that the total number of possible rules is factorial in the size of the candidate set. We address this problem by limiting the number of variables and the recursion depth, and by filtering out singleton rules.

There is no guarantee that the induced rules will generalise well to a testing set. For example, the testing data may have a rule which was not seen in the training set (*e.g.,* a new terminal or non terminal). In this case no rule can be applied and subsequently generation fails. For this reason we allow the model to duplicate any CFG production from the source tree, and uses a feature to flag that this rule was unseen in training. These SCFG rules are then merged with the induced rules and fed into the feature detection module (see Section 3.3 for details).



$$\begin{aligned}
\langle S,S\rangle &\rightarrow \langle [NP_{\boxed{1}}\, VP_{\boxed{2}}\ \cdot_{\boxed{3}}]_S, [NP_{\boxed{1}}\, VP_{\boxed{2}}\ \cdot_{\boxed{3}}]_S\rangle \\
\langle NP,NP\rangle &\rightarrow \langle [DT\ NN_{\boxed{1}}]_{NP}, [NN_{\boxed{1}}]_{NP}\rangle \\
\langle NN,NN\rangle &\rightarrow \langle \text{documentation}_{NN}, \text{Documentation}_{NN}\rangle \\
\langle VP,VP\rangle &\rightarrow \langle VP_{\boxed{1}}\, CC\ VP, VP_{\boxed{1}}\rangle \\
\langle VP,VP\rangle &\rightarrow \langle AUX_{\boxed{1}}\, ADJP_{\boxed{2}}, AUX_{\boxed{1}}\, ADJP_{\boxed{2}}\rangle \\
\langle AUX,AUX\rangle &\rightarrow \langle \text{is}_{AUX}, \text{is}_{AUX}\rangle \\
\langle ADJP,ADJP\rangle &\rightarrow \langle [RB_{\boxed{1}}\, JJ_{\boxed{2}}]_{ADJP}, [RB_{\boxed{1}}\, JJ_{\boxed{2}}]_{ADJP}\rangle \\
\langle RB,RB\rangle &\rightarrow \langle \text{very}_{RB}, \text{very}_{RB}\rangle \\
\langle JJ,JJ\rangle &\rightarrow \langle \text{good}_{ADJ}, \text{good}_{ADJ}\rangle \\
\langle .,.\rangle &\rightarrow \langle ..,..\rangle
\end{aligned}$$

Figure 3: Induced synchronous grammar from a sentence pair using a strategy that extracts general rules.

3.3 The Large Margin Model

We now describe how the parameters of our STSG generation system are fit to a supervised training set. For a given source tree, the space of sister target trees implied by the synchronous grammar is often very large, and the majority of these trees are ungrammatical or are poor compressions. The training procedure learns weights such that the model can discriminate between these trees and predict a good target tree. For this we develop a discriminative training process which learns a weighted tree-to-tree transducer. Our model is based on Tsochantaridis et al.'s (2005) framework for learning Support Vector Machines (SVMs) with structured output spaces, using the SVM^{struct} implementation.[1] We briefly summarise the approach below; for a more detailed description we refer the interested reader to Tsochantaridis et al. (2005).

Traditionally SVMs learn a linear classifier that separates two or more classes with the largest possible margin. Analogously, structured SVMs attempt to separate the correct structure from all other

[1] http://svmlight.joachims.org/svm_struct.html

structures with a large margin. Given an input instance **x**, we search for the optimum output **y** under the assumption that **x** and **y** can be adequately described using a combined feature vector representation $\Psi(\mathbf{x},\mathbf{y})$. Recall that **x** are the source trees and **y** are synchronous derivations which generate both **x** and a target tree.

$$f(\mathbf{x};\mathbf{w}) = \underset{y\in\mathcal{Y}}{\operatorname{argmax}}\langle\mathbf{w},\Psi(\mathbf{x},\mathbf{y})\rangle \tag{2}$$

The goal of the training procedure is to find a parameter vector **w** such that it satisfies the condition:

$$\forall i, \forall y \in \mathcal{Y}\backslash y_i : \langle\mathbf{w},\Psi(\mathbf{x}_i,\mathbf{y}_i) - \Psi(\mathbf{x}_i,\mathbf{y})\rangle \geq 0 \tag{3}$$

where $\mathbf{x}_i, \mathbf{y}_i$ are the ith training source tree and target derivation. To obtain a unique solution — there will be several parameter vectors **w** satisfying (3) if the training instances are linearly separable — Tsochantaridis et al. (2005) select the **w** that maximises the minimum distance between $\mathbf{y}_i$ and the closest runner-up structure.

The framework also incorporates a loss function. This property is particularly appealing in the context of sentence compression and generally text-to-text generation. For example, a compression that differs from the gold standard with respect to one or two words should be treated differently from a compression that bears no resemblance to it. Another important factor is the length of the compression. Compressions whose length is similar to the gold standard should be be preferable to longer or shorter output. A loss function $\Delta(\mathbf{y}_i,\mathbf{y})$ quantifies the accuracy of prediction **y** with respect to the true output value $\mathbf{y}_i$. We give details of the loss functions we employed for the compression task below.

We are now ready to state the learning objective for the structured SVM. We use the soft-margin formulation which allows errors in the training set, via the slack variables ξ_i:

$$\min_{\mathbf{w},\xi} \frac{1}{2}||\mathbf{w}||^2 + \frac{C}{n}\sum_{i=1}^{n}\xi_i,\ \xi_i \geq 0 \tag{4}$$

$$\forall i, \forall \mathbf{y} \in \mathcal{Y}\backslash \mathbf{y}_i : \langle\mathbf{w},\delta\Psi(\mathbf{y})\rangle \geq 1 - \frac{\xi_i}{\Delta(\mathbf{y}_i,\mathbf{y})}$$

Slack variables ξ_i are introduced here for each training example x_i, C is a constant that controls the trade-off between training error minimisation and margin maximisation, and $\delta\Psi(\mathbf{y})$ is a shorthand for $\Psi(\mathbf{x}_i,\mathbf{y}_i) - \Psi(\mathbf{x}_i,\mathbf{y})$ (see (3)). Note that slack variables are rescaled with the inverse loss incurred in each of the linear constraints.[2]

The optimisation problem in (4) is approximated using a polynomial time cutting plane algorithm (Tsochantaridis et al., 2005). This optimisation crucially relies on finding the constraint incurring the maximum cost. The cost function for slack rescaling can be formulated as:

$$H(\mathbf{y}) = (1 - \langle\delta\Psi_i(\mathbf{y}),\mathbf{w}\rangle)\Delta(\mathbf{y}_i,\mathbf{y}) \tag{5}$$

In order to adapt this framework to our generation problem, we must provide the feature mapping $\Psi(\mathbf{x},\mathbf{y})$, a loss function $\Delta(\mathbf{y}_i,\mathbf{y})$, and a maximiser $\hat{\mathbf{y}} = \operatorname{argmax}_{\mathbf{y}\in\mathcal{Y}} H(\mathbf{y})$ (see (5)). The following sections describe how these are instantiated in the sentence compression task.

Feature Mapping We devised a general feature set suitable for compression and paraphrasing. Our feature space is defined over source trees (**x**) and target derivations (**y**). All features apply to a single grammar rule; a feature vector for a derivation is expressed as the sum of the feature vectors for each rule in this derivation.

We make use of syntactic, lexical, and compression specific features. Our simplest syntactic feature is the identity of a synchronous rule. Specifically, we record its source tree, its target tree and their combination. We also include rule frequencies $\phi(\mathit{target}|\mathit{source})$, $\phi(\mathit{source}|\mathit{target})$ and $\phi(\mathit{source},\mathit{target})$. Another feature records the frequencies of the CFG productions used in the target side of a rule. This allows the model to learn the weights of a CFG generation grammar, as a proxy for a language model. Using scores from a pre-trained CFG grammar or an n-gram language model might be preferable when the training sample is small, however we leave this as future work. Our last syntactic feature keeps track of the source root and the target root non-terminals. Our lexical features contain the list of tokens in the source yield, target yield, and both. We also use words as features.

[2] Alternatively, the loss function can be used to rescale the margin. This approach is less desirable as it is not scale invariant (Tsochantaridis et al., 2005). We also found empirically that slack-rescaling slightly outperforms margin rescaling on our compression task.

Finally, we have implemented a set of compression-specific features. These include a feature that detects if the yield of the target side of a synchronous rule is a subset of the yield of its source. We also take note of the edit operations (i.e., removal, insertion) required to transform the source side into the target. Edit operations are recorded separately for trees and their yields. In order to encourage compression, we also count the number of words on the target, the number of rules used in the derivation and the number of dropped variables.

Loss Functions The large margin configuration sketched above is quite modular and in theory a wide range of loss functions could be specified. Examples include edit-distance, precision, F-score, BLEU and tree-based measures. In practice, the loss function should be compatible with our maximisation algorithm which requires the objective function to decompose along the same lines as the tree derivation.[3]

Given this restriction, we define a loss based on position-independent unigram precision (Prec) which penalises errors in the yield independently for each word. Although fairly intuitive, this loss is far from ideal. First, it maximally rewards repeatedly predicting the same word if the latter is in the reference target tree. Secondly, it may bias towards overly short output which drops core information — one-word compressions will tend to have higher precision than longer output. To counteract this, we introduce two brevity penalty measures (BP) inspired by BLEU (Papineni et al., 2002) which we incorporate into the loss function, using a product, $loss = 1 - \text{Prec} \cdot \text{BP}$:

$$\begin{aligned} \text{BP1} &= \exp(1 - \max(1, \frac{r}{c})) \qquad (6) \\ \text{BP2} &= \exp(1 - \max(\frac{c}{r}, \frac{r}{c})) \end{aligned}$$

where r is the reference length and c is the candidate length.

BP1 is asymmetric, it has value one when $c \geq r$ and decays to zero when $c < r$. Note that precision should decay when $c > r$ as extra output will often not match the reference. BP2 is two-sided: it has value one when $c = r$ and decays towards zero for $c < r$ and $c > r$. In both cases, brevity is assessed against the gold standard target (not the source) to allow the system to learn the correct degree of compression from the training data.

Maximisation Algorithm Our algorithm finds the maximising derivation for $H(\mathbf{y})$ in (5). This derivation will have a high loss and a high score under the model, and therefore represents the most-violated constraint which is then added to the SVM's working set of constraints (see (4)).

The standard generation method from Section 3.1 cannot be used without modification to find the best scoring derivation since it does not account for the loss function or the gold standard derivation. Instead, we *stratify* the generation chart with the number of true and false positive tokens predicted, as described in Joachims (2005). These contingency values allow us to compute the precision and brevity penalty (see (6)) for each complete derivation. This is then combined with the derivation score and the gold standard derivation score to give $H(\mathbf{y})$.

The gold standard derivation features, $\Psi(\mathbf{x}_i, \mathbf{y}_i)$, must be calculated from a derivation linking the source tree to the gold target tree. As there may be many such derivations, we find a *unique* derivation using the smallest rules possible (for maximum generality). This is done using a dynamic program, similar to the inside-outside algorithm used in parsing. Other strategies are also possible, however we leave this to future work. Finally, we can find the global maximum $H(\mathbf{y})$ by maximising over all the root chart entries.

4 Evaluation Set-up

In this section we present our experimental set-up for assessing the performance of the max margin model described above. We give details of the corpora used, briefly introduce McDonald's (2006) sentence compression model used for comparison with our approach, and explain how system output was evaluated.

Corpora We evaluated our system on two different corpora. The first is the compression corpus of Knight and Marcu (2002) derived automatically from the document-abstract pairs of the Ziff-

[3] Optimising non-decompositional loss functions complicates the objective function, which then cannot be solved efficiently using a dynamic program.

Davis corpus. Previous compression work has almost exclusively used this corpus. Our experiments follow Knight and Marcu's partition of training, test, and development sets (1,002/36/12 instances). We also present results on Clarke and Lapata's (2006a) Broadcast News corpus.[4] This corpus was created manually (annotators were asked to produce compressions for 50 Broadcast news stories) and poses more of a challenge than Ziff-Davis. Being a speech corpus, it often contains incomplete and ungrammatical utterances and speech artefacts such as disfluencies, false starts and hesitations. Furthermore, spoken utterances have varying lengths, some are very wordy whereas others cannot be reduced any further. Thus a hypothetical compression system trained on this domain should be able to leave some sentences uncompressed. Again we used Clarke and Lapata's training, test, and development set split (882/410/78 instances).

Comparison with State-of-the-art We evaluated our approach against McDonald's (2006) discriminative model. This model is a good basis for comparison for several reasons. First, it achieves competitive performance with Knight and Marcu's (2002) decision tree and noisy channel models. Second, it also uses large margin learning. Sentence compression is formulated as a string-to-substring mapping problem with a deletion-based Hamming loss. Recall that our formulation involves a tree-to-tree mapping. Third, it uses a feature space complementary to ours. For example features are defined between adjacent words, and syntactic evidence is incorporated indirectly into the model. In contrast our model relies on synchronous rules to generate valid compressions and does not explicitly incorporate adjacency features. We used an implementation of McDonald (2006) for comparison of results (Clarke and Lapata, 2007).

Evaluation Measures In line with previous work we assessed our model's output by eliciting human judgements. Participants were presented with an original sentence and its compression and asked to rate the latter on a five point scale based on the information retained and its grammaticality. We conducted two separate elicitation studies, one for the Ziff-Davis and one for the Broadcast news dataset. In both cases our materials consisted of 96 source-target sentences. These included gold standard compressions and the output of our system and McDonald's (2006). We were able to obtain ratings on the entire Ziff-Davis test set as it has only 32 instances; this was not possible for Broadcast news as the test section consists of 410 instances. Consequently, we randomly selected 32 source-target sentences to match the size of the Ziff-Davis test set.[5] We collected ratings from 60 unpaid volunteers, all self reported native English speakers. Both studies were conducted over the Internet. Examples of our experimental items are given in Table 1.

G:	In a conference call with analysts the bank said it boosted credit card reserves by $350 million.

Table 1: Compression examples from the Broadcast news corpus (O: original sentence, M: McDonald (2006), S: STSG, G: gold standard)

We also report results using F1 computed over grammatical relations (Riezler et al., 2003). We chose F1 (as opposed to accuracy or edit distance-based measures) as Clarke and Lapata (2006b) show that it correlates reliably with human judgements.

5 Experiments

The framework presented in Section 3 is quite flexible. Depending on the grammar induction strategy, choice of features, loss function and maximisation algorithm, different classes of models can be derived. Before presenting our results in detail we discuss the specific model employed in our experiments and explain how its parameters were instantiated.

In order to build a compression model we need

[4] The corpus can be downloaded from `http://homepages.inf.ed.ac.uk/s0460084/data/`.

[5] A Latin square design ensured that subjects did not see two different compressions of the same sentence.

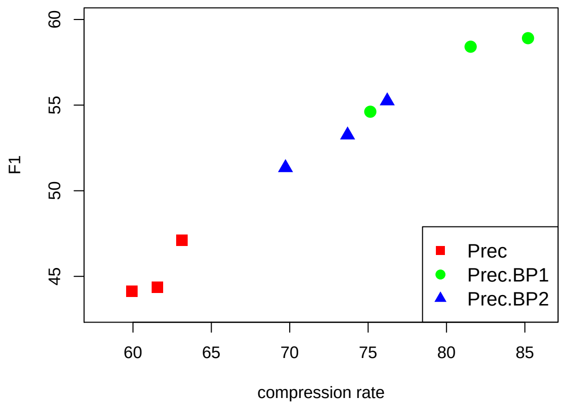

Figure 4: Compression rate vs. grammatical relations F1 using unigram precision alone and in combination with two brevity penalties.

a parallel corpus of syntax trees. We obtained syntactic analyses for source and target sentences with Bikel's (2002) parser. Our corpora were automatically aligned with Giza++ (Och et al., 1999) in both directions between source and target and symmetrised using the intersection heuristic (Koehn et al., 2003). Each word in the lexicon was also aligned with itself. This was necessary in order to inform Giza++ about word identity. Unparseable sentences and those longer than 50 tokens were removed from the data set.

We induced a synchronous tree substitution grammar from the Ziff-Davis and Broadcast news corpora using the method described in Section 3.2. We extracted all maximally general synchronous rules. These were complemented with more specific rules from conjoining pairs of general rules. The specific rules were pruned to remove singletons and those rules with more than 3 variables. Grammar rules were represented by the features described in Section 3.3.

An important parameter for our compression task is the appropriate choice of loss function. Ideally, we would like a loss function that encourages compression without overly aggressive information loss. Figure 4 plots compression rate against grammatical relations F1 using each of the loss functions presented in Section 3.3 on the Ziff-Davis development set.[6] As can be seen with unigram precision alone (Prec) the system produces overly short output, whereas the one-sided brevity penalty (BP1) achieves the opposite effect. The two-sided brevity penalty (BP2) seems to strike the right balance: it encourages compression while achieving good F-scores. This suggests that important information is retained in spite of significant compression. We also varied the regularisation parameter C (see (4)) over a range of values on the development set and found that setting it to 0.01 yields overall good performance across corpora and loss functions.

Ziff-Davis	CompR	RelF1
McDonald06	66.2	45.8
STSG	56.8	54.3
Gold standard	57.2	—

Broadcast News	CompR	RelF1
McDonald06	68.6	47.6
STSG	73.7	53.4*
Gold standard	76.1	—

Table 2: Results using grammatical relations F1 (*: sig. diff. from McDonald06; $p < 0.01$ using the Student t test)

We now present our results on the test set. These were obtained with a model that uses slack rescaling and a precision-based loss function with a two-sided brevity penalty ($C = 0.01$). Table 2 shows the average compression rates (CompR) for McDonald (2006) and our model (STSG) as well as their performance according to grammatical relations F1. The row 'Gold standard' displays human-produced compression rates. Notice that our model obtains compression rates similar to the gold standard, whereas McDonald tends to compress less on Ziff-Davis and more on Broadcast news. As far as F1 is concerned, we see that STSG outperforms McDonald on both corpora. The difference in F1 is statistically significant on Broadcast news but not on Ziff-Davis (which consists solely of 32 sentences).

Table 3 presents the results of our elicitation study. We carried out an Analysis of Variance (ANOVA) to examine the effect of system type (McDonald06, STSG, Gold standard) on the compression ratings. The ANOVA revealed a reliable effect on both corpora. We used post-hoc Tukey tests to

[6] We obtained a similar plot for the Broadcast News corpus but omit it due to lack of space.

Model	Ziff-Davis	Broadcast news
McDonald06	2.82[†]	2.16[†]
STSG	3.20[†*]	2.63[*]
Gold standard	3.72	3.05

Table 3: Mean ratings on compression output elicited by humans ([*]: sig. diff. from McDonald06 ($\alpha < 0.05$); [†] sig. diff. from Gold standard ($\alpha < 0.01$); using post-hoc Tukey tests)

examine whether the mean ratings for each system differed significantly. The Tukey tests showed that STSG is perceived as significantly better than McDonald06. There is no significant difference between STSG and the gold standard compressions on the Broadcast news; both systems are significantly worse than the gold standard on Ziff-Davis.

These results are encouraging, indicating that our highly expressive framework is a good model for sentence compression. Under several experimental conditions we obtain better performance than previous work. Importantly, the model described here is not compression-specific, it could be easily adapted to other tasks, corpora or languages (for which syntactic analysis tools are available). Being supervised, our model learns to fit the compression rate of the training data. In this sense, it is somewhat inflexible as it cannot easily adapt to a specific rate given by a user or imposed by an application (*e.g.,* when displaying text on small screens). Compression rate can be indirectly manipulated by adopting loss functions that encourage or discourage compression (see Figure 4), but admittedly in other frameworks (*e.g.,* Clarke and Lapata (2006a)) the length of the compression can be influenced more naturally.

In our formulation of the compression problem, a derivation is characterised by a single inventory of features. This entails that the feature space cannot in principle distinguish between derivations that use the same rules, applied in a different order. Although, this situation does not arise often in our dataset, we believe that it can be ameliorated by intersecting a language model with our generation algorithm (Chiang, 2005).

6 Conclusions and Future Work

In this paper we have presented a novel method for sentence compression cast in the framework of structured learning. We develop a system that generates compressions using a synchronous tree substitution grammar whose weights are discriminatively trained within a large margin model. We also describe an appropriate algorithm than can be used in both training (i.e., learning the model weights) and decoding (i.e., finding the most plausible compression under the model). The proposed formulation allows us to capture rewriting operations that go beyond word deletion and can be easily tuned to specific loss functions directly related to the problem at hand. We empirically evaluate our approach against a state-of-the art model (McDonald, 2006) and show performance gains on two compression corpora.

Future research will follow three directions. First, we will extend the framework to incorporate position dependent loss functions. Examples include the Hamming distance or more sophisticated functions that take the tree structure of the source and target sentences into account. Such functions can be supported by augmenting our generation algorithm with a beam search. Secondly, the present paper used a relatively simple feature set. Our intention was to examine our model's performance without extensive feature engineering. Nevertheless, improvements should be possible by incorporating features defined over *n*-grams and dependencies (McDonald, 2006). Finally, the experiments presented in this work use a grammar acquired from the training corpus. However, there is nothing inherent in our formalisation that restricts us to this particular grammar. We therefore plan to investigate the potential of our method with unsupervised or semi-supervised grammar induction techniques for additional rewriting tasks including paraphrase generation and machine translation.

Incremental Text Structuring with Online Hierarchical Ranking

Erdong Chen, Benjamin Snyder and Regina Barzilay

Abstract

Many emerging applications require documents to be repeatedly updated. Such documents include newsfeeds, webpages, and shared community resources such as Wikipedia. In this paper we address the task of inserting new information into existing texts. In particular, we wish to determine the best location in a text for a given piece of new information. For this process to succeed, the insertion algorithm should be informed by the existing document structure. Lengthy real-world texts are often hierarchically organized into chapters, sections, and paragraphs. We present an online ranking model which exploits this hierarchical structure – representationally in its features and algorithmically in its learning procedure. When tested on a corpus of Wikipedia articles, our hierarchically informed model predicts the correct insertion paragraph more accurately than baseline methods.

1 Introduction

Many emerging applications require documents to be repeatedly updated. For instance, newsfeed articles are continuously revised by editors as new information emerges, and personal webpages are modified as the status of the individual changes. This revision strategy has become even more prevalent with the advent of community edited web resources, the most notable example being Wikipedia. At present this process involves massive human effort. For instance, the English language version of Wikipedia averaged over 3 million edits[1] per month in 2006. Even so, many articles quickly become outdated. A system that performs such updates automatically could drastically decrease maintenance efforts and potentially improve document quality.

Currently there is no effective way to automatically update documents as new information becomes available. The closest relevant text structuring technique is the work on sentence ordering, in which a complete reordering of the text is undertaken. Predictably these methods are suboptimal for this new task because they cannot take advantage of existing text structure.

We introduce an alternative vision of text structuring as a process unfolding over time. Instead of ordering sentences all at once, we start with a well-formed draft and add new information at each stage, while preserving document coherence. The basic operation of incremental text structuring is the insertion of new information. To automate this process, we develop a method for determining the best location in a text for a given piece of new information.

The main challenge is to maintain the continuity and coherence of the original text. These properties may be maintained by examining sentences adjacent to each potential insertion point. However, a local sentence comparison method such as this may fail to account for global document coherence (e.g. by allowing the mention of some fact in an inappropriate section). This problem is especially acute in the case of lengthy, real-world texts such as books, technical reports, and web pages. These documents

are commonly organized hierarchically into sections and paragraphs to aid reader comprehension. For documents where hierarchical information is not explicitly provided, such as automatic speech transcripts, we can use automatic segmentation methods to induce such a structure (Hearst, 1994). Rather than ignoring the inherent hierarchical structure of these texts, we desire to directly model such hierarchies and use them to our advantage – both representationally in our features and algorithmically in our learning procedure.

To achieve this goal, we introduce a novel method for sentence insertion that operates over a hierarchical structure. Our document representation includes features for each layer of the hierarchy. For example, the word overlap between the inserted sentence and a section header would be included as an upper-level section feature, whereas a comparison of the sentence with all the words in a paragraph would be a lower-level paragraph feature. We propose a linear model which simultaneously considers the features of every layer when making insertion decisions. We develop a novel update mechanism in the online learning framework which exploits the hierarchical decomposition of features. This mechanism limits model updates to those features found at the highest incorrectly predicted layer, without unnecessarily disturbing the parameter values for the lower reaches of the tree. This conservative update approach maintains as much knowledge as possible from previously encountered training examples.

We evaluate our method using real-world data where multiple authors have revised preexisting documents over time. We obtain such a corpus from Wikipedia articles,[2] which are continuously updated by multiple authors. Logs of these updates are publicly available, and are used for training and testing of our algorithm. Figure 1 shows an example of a Wikipedia insertion. We believe this data will more closely mirror potential applications than synthetic collections used in previous work on text structuring.

Our hierarchical training method yields significant improvement when compared to a similar non-hierarchical model which instead uses the standard perceptron update of Collins (2002). We also report human performance on the insertion task in order to provide a reasonable upper-bound on machine performance. An analysis of these results shows that our method closes the gap between machine and human performance substantially.

In the following section, we provide an overview of existing work on text structuring and hierarchical learning. Then, we define the insertion task and introduce our hierarchical ranking approach to sentence insertion. Next, we present our experimental framework and data. We conclude the paper by presenting and discussing our results.

2 Related Work

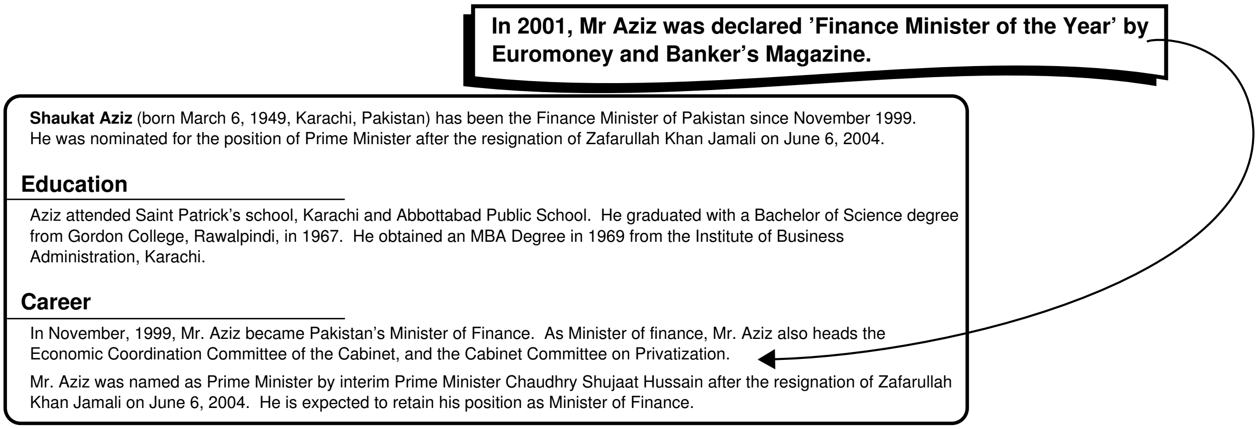
Text Structuring The insertion task is closely related to the extensively studied problem of sentence ordering.[3] Most of the existing algorithms represent text structure as a linear sequence and are driven by local coherence constraints (Lapata, 2003; Karamanis et al., 2004; Okazaki et al., 2004; Barzilay and Lapata, 2005; Bollegala et al., 2006; Elsner and Charniak, 2007). These methods induce a total ordering based on pairwise relations between sentences. Researchers have shown that identifying precedence relations does not require deep semantic interpretation of input sentences: shallow distributional features are sufficient for accurate prediction. Our approach employs similar features to represent nodes at the lowest level of the hierarchy.

The key departure of our work from previous research is the incorporation of hierarchical structure into a corpus-based approach to ordering. While in symbolic generation and discourse analysis a text is typically analyzed as a tree-like structure (Reiter and Dale, 1990), a linear view is prevalent in data-driven methods to text structuring.[4] Moving beyond a linear representation enables us to handle longer texts where a local view of coherence does not suffice. At the same time, our approach does not require any manual rules for handling tree insertions, in contrast to symbolic text planners.

[2] Data and code used in this paper are available at `http://people.csail.mit.edu/edc/emnlp07/`

[3] Independently and simultaneously with our work, Elsner and Charniak (2007) have studied the sentence insertion task in a different setting.

[4] Though statistical methods have been used to induce such trees (Soricut and Marcu, 2003), they are not used for ordering and other text-structuring tasks.



In 2001, Mr Aziz was declared ’Finance Minister of the Year’ by Euromoney and Banker’s Magazine.

Shaukat Aziz (born March 6, 1949, Karachi, Pakistan) has been the Finance Minister of Pakistan since November 1999. He was nominated for the position of Prime Minister after the resignation of Zafarullah Khan Jamali on June 6, 2004.

Education

Aziz attended Saint Patrick’s school, Karachi and Abbottabad Public School. He graduated with a Bachelor of Science degree from Gordon College, Rawalpindi, in 1967. He obtained an MBA Degree in 1969 from the Institute of Business Administration, Karachi.

Career

In November, 1999, Mr. Aziz became Pakistan’s Minister of Finance. As Minister of finance, Mr. Aziz also heads the Economic Coordination Committee of the Cabinet, and the Cabinet Committee on Privatization.

Mr. Aziz was named as Prime Minister by interim Prime Minister Chaudhry Shujaat Hussain after the resignation of Zafarullah Khan Jamali on June 6, 2004. He is expected to retain his position as Minister of Finance.

Hierarchical Learning There has been much recent research on multiclass hierarchical classification. In this line of work, the set of possible labels is organized hierarchically, and each input must be assigned a node in the resulting tree. A prototype weight vector is learned for each node, and classification decisions are based on all the weights along the path from node to root. The essence of this scheme is that the more ancestors two nodes have in common, the more parameters they are forced to share. Many learning methods have been proposed, including SVM-style optimization (Cai and Hofmann, 2004), incremental least squares estimation (Cesa-Bianchi et al., 2006b), and perceptron (Dekel et al., 2004).

This previous work rests on the assumption that a predetermined set of atomic labels with a fixed hierarchy is given. In our task, however, the set of possible insertion points – along with their hierarchical organization – is unique to each input document. Furthermore, nodes exhibit rich internal feature structure and cannot be identified across documents, except insofar as their features overlap. As is commonly done in NLP tasks, we make use of a feature function which produces one feature vector for each possible insertion point. We then choose among these feature vectors using a single weight vector (casting the task as a *structured ranking* problem rather than a *classification* problem). In this framework, an explicit hierarchical view is no longer necessary to achieve parameter tying. In fact, each parameter will be shared by exactly those insertion points which exhibit the corresponding feature, both across documents and within a single document. Higher level parameters will thus naturally be shared by all paragraphs within a single section.

In fact, when the perceptron update rule of (Dekel et al., 2004) – which modifies the weights of every divergent node along the predicted and true paths – is used in the ranking framework, it becomes virtually identical with the standard, flat, ranking perceptron of Collins (2002).[5] In contrast, our approach shares the idea of (Cesa-Bianchi et al., 2006a) that “if a parent class has been predicted wrongly, then errors in the children should not be taken into account.” We also view this as one of the key ideas of the incremental perceptron algorithm of (Collins and Roark, 2004), which searches through a complex decision space step-by-step and is immediately updated at the first wrong move.

Our work fuses this idea of selective hierarchical updates with the simplicity of the perceptron algorithm and the flexibility of arbitrary feature sharing inherent in the ranking framework.

3 The Algorithm

In this section, we present our sentence insertion model and a method for parameter estimation. Given a hierarchically structured text composed of sections and paragraphs, the sentence insertion model determines the best paragraph within

[5] The main remaining difference is that Dekel et al. (2004) use a passive-aggressive update rule (Crammer et al., 2006) and in doing so enforce a margin based on tree distance.

which to place the new sentence. To identify the exact location of the sentence within the chosen paragraph, local ordering methods such as (Lapata, 2003) could be used. We formalize the insertion task as a structured ranking problem, and our model is trained using an online algorithm. The distinguishing feature of the algorithm is a selective correction mechanism that focuses the model update on the relevant layer of the document's feature hierarchy.

The algorithm described below can be applied to any hierarchical ranking problem. For concreteness, we use the terminology of the sentence insertion task, where a hierarchy corresponds to a document with sections and paragraphs.

3.1 Problem Formulation

In a sentence insertion problem, we are given a training sequence of instances $(s^1, \mathcal{T}^1, \ell^1), \ldots, (s^m, \mathcal{T}^m, \ell^m)$. Each instance contains a sentence s, a hierarchically structured document $\mathcal{T}$, and a node ℓ representing the correct insertion point of s into $\mathcal{T}$. Although ℓ can generally be any node in the tree, in our problem we need only consider leaf nodes. We cast this problem in the ranking framework, where a feature vector is associated with each sentence-node pair. For example, the feature vector of an internal, section-level node may consider the word overlap between the inserted sentence and the section title. At the leaf level, features may include an analysis of the overlap between the corresponding text and sentence. In practice, we use disjoint feature sets for different layers of the hierarchy, though in theory they could be shared.

Our goal then is to choose a leaf node by taking into account its feature vector as well as feature vectors of all its ancestors in the tree.

More formally, for each sentence s and hierarchically structured document $\mathcal{T}$, we are given a set of feature vectors, with one for each node: $\{\phi(s,n) : n \in \mathcal{T}\}$. We denote the set of leaf nodes by $\mathcal{L}(\mathcal{T})$ and the path from the root of the tree to a node n by $\mathcal{P}(n)$. Our model must choose one leaf node among the set $\mathcal{L}(\mathcal{T})$ by examining its feature vector $\phi(s,\ell)$ as well as all the feature vectors along its path: $\{\phi(s,n) : n \in \mathcal{P}(\ell)\}$.

```
Input : $(s^1, \mathcal{T}^1, \ell^1), \ldots, (s^m, \mathcal{T}^m, \ell^m)$.
Initialize : Set $\mathbf{w}^1 = 0$
Loop : For $t = 1, 2, ..., N$ :
  1. Get a new instance $s^t, \mathcal{T}^t$.
  2. Predict $\hat{\ell}^t = \arg\max_{\ell \in \mathcal{L}(\mathcal{T})} \mathbf{w}^t \cdot \Phi(s^t, \ell)$.
  3. Get the new label $\ell^t$.
  4. If $\hat{\ell}^t = \ell^t$:
       $\mathbf{w}^{t+1} \leftarrow \mathbf{w}^t$
     Else:
       $i^* \leftarrow \max\{i : \mathcal{P}(\ell^t)^i = \mathcal{P}(\hat{\ell}^t)^i\}$
       $a \leftarrow \mathcal{P}(\ell^t)^{i^*+1}$
       $b \leftarrow \mathcal{P}(\hat{\ell}^t)^{i^*+1}$
       $\mathbf{w}^{t+1} \leftarrow \mathbf{w}^t + \phi(s,a) - \phi(s,b)$
Output : $\mathbf{w}^{N+1}$.
```

Figure 2: Training algorithm for the hierarchical ranking model.

3.2 The Model

Our model consists of a weight vector $\mathbf{w}$, each weight corresponding to a single feature. The features of a leaf are aggregated with the features of all its ancestors in the tree. The leaf score is then computed by taking the inner product of this aggregate feature vector with the weights $\mathbf{w}$. The leaf with the highest score is then selected.

More specifically, we define the *aggregate feature vector* of a leaf ℓ to be the sum of all features found along the path to the root:

$$\Phi(s,\ell) = \sum_{n \in \mathcal{P}(\ell)} \phi(s,n) \tag{1}$$

This has the effect of *stacking together* features found in a single layer, and *adding* the values of features found at more than one layer.

Our model then outputs the leaf with the highest scoring aggregate feature vector:

$$\arg\max_{\ell \in \mathcal{L}(\mathcal{T})} \mathbf{w} \cdot \Phi(s,\ell) \tag{2}$$

Note that by using this criterion, our decoding method is equivalent to that of the standard linear ranking model. The novelty of our approach lies in our training algorithm which uses the hierarchical feature decomposition of Equation 1 to pinpoint its updates along the path in the tree.

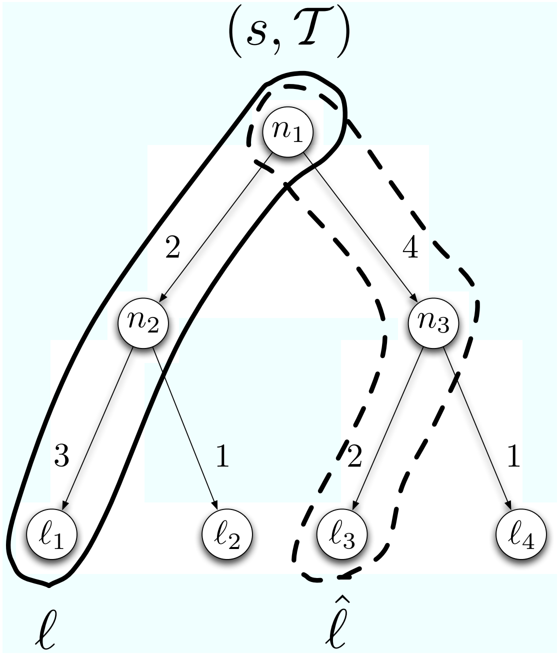

Figure 3: An example of a tree with the corresponding model scores. The path surrounded by solid lines leads to the correct node ℓ_1. The path surrounded by dotted lines leads to ℓ_3, the predicted output based on the current model.

3.3 Training

Our training procedure is implemented in the online learning framework. The model receives each training instance, and predicts a leaf node according to its current parameters. If an incorrect leaf node is predicted, the weights are updated based on the divergence between the predicted path and the true path. We trace the paths down the tree, and only update the weights of the features found at the split point. Updates for shared nodes along the paths would of course cancel out. In contrast to the standard ranking perceptron as well as the hierarchical perceptron of (Dekel et al., 2004), no features further down the divergent paths are incorporated in the update. For example, if the model incorrectly predicts the section, then only the weights of the section features are updated whereas the paragraph feature weights remain untouched.

More formally, let $\hat{\ell}$ be the predicted leaf node and let $\ell \neq \hat{\ell}$ be the true leaf node. Denote by $\mathcal{P}(\ell)^i$ the i^{th} node on the path from the root to ℓ. Let i^* be the depth of the lowest common ancestor of ℓ and $\hat{\ell}$ (i.e., $i^* = \max\{i : \mathcal{P}(\ell)^i = \mathcal{P}(\hat{\ell})^i\}$). Then the update rule for this round is:

$$\mathbf{w} \leftarrow \mathbf{w} + \phi\left(s, \mathcal{P}(\ell)^{i^*+1}\right) - \phi\left(s, \mathcal{P}(\hat{\ell})^{i^*+1}\right) \quad (3)$$

Full pseudo-code for our hierarchical online training algorithm is shown in Figure 2.

We illustrate the selective update mechanism on the simple example shown on Figure 3. The correct prediction is the node ℓ_1 with an aggregate path score of 5, but ℓ_3 with the higher score of 6 is predicted. In this case, both the section and the paragraph are incorrectly predicted. In response to this mistake, the features associated with the correct section, n_2, are added to the weights, and the features of the incorrectly predicted section, n_3, are subtracted from the weights. An alternative update strategy would be to continue to update the feature weights of the leaf nodes, ℓ_1 and ℓ_3. However, by identifying the exact source of path divergence we preserve the previously learned balance between leaf node features.

4 Features

Features used in our experiments are inspired by previous work on corpus-based approaches for discourse analysis (Marcu and Echihabi, 2002; Lapata, 2003; Elsner et al., 2007). We consider three types of features: lexical, positional, and temporal. This section gives a general overview of these features (see code for further details.)

Lexical Features Lexical features have been shown to provide strong cues for sentence positioning. To preserve text cohesion, an inserted sentence has to be topically close to its surrounding sentences. At the paragraph level, we measure topical overlap using the TF*IDF weighted cosine similarity between an inserted sentence and a paragraph. We also use a more linguistically refined similarity measure that computes overlap considering only subjects and objects. Syntactic analysis is performed using the MINIPAR parser (Lin, 1998).

The overlap features are computed at the section level in a similar way. We also introduce an additional section-level overlap feature that computes the cosine similarity between an inserted sentence and the first sentence in a section. In our corpus, the opening sentence of a section is typically strongly indicative of its topic, thus providing valuable cues for section level insertions.

In addition to overlap, we use lexical features that capture word co-occurrence patterns in coherent texts. This measure was first introduced in the context of sentence ordering by Lapata (2003). Given a collection of documents in a specific domain, we compute the likelihood that a pair of words co-occur in adjacent sentences. From these counts, we induce the likelihood that two sentences are adjacent to each other. For a given paragraph and an inserted sentence, the highest adjacency probability between the inserted sentence and paragraph sentences is recorded. This feature is also computed at the section level.

Positional Features These features aim to capture user preferences when positioning new information into the body of a document. For instance, in the Wikipedia data, insertions are more likely to appear at the end of a document than at its beginning. We track positional information at the section and paragraph level. At the section level, we record whether a section is the first or last of the document. At the paragraph level, there are four positional features which indicate the paragraph's position (i.e., start or end) within its individual section and within the document as a whole.

Temporal Features The text organization may be influenced by temporal relations between underlying events. In temporally coherent text, events that happen in the same time frame are likely to be described in the same segment. Our computation of temporal features does not require full fledged temporal interpretation. Instead, we extract these features based on two categories of temporal cues: verb tense and date information. The verb tense feature captures whether a paragraph contains at least one sentence using the same tense as the inserted sentence. For instance, this feature would occur for the inserted sentence in Figure 1 since both the sentence and chosen paragraph employ the past tense.

Another set of features takes into account the relation between the dates in a paragraph and those in an inserted sentence. We extract temporal expressions using the **TIMEX2** tagger (Mani and Wilson, 2000), and compute the time interval for a paragraph bounded by its earliest and latest dates. We record the degree of overlap between the paragraph time interval and insertion sentence time interval.

		Section	Paragraph	Tree Dist
T1	J1	0.575	0.5	1.85
	J2	0.7	0.525	1.55
T2	J3	0.675	0.55	1.55
	J4	0.725	0.55	1.45

Table 1: Accuracy of human insertions compared against gold standard from Wikipedia's update log. T1 is a subset of the data annotated by judges J1 and J2, while T2 is annotated by J3 and J4.

5 Experimental Set-Up

Corpus Our corpus consists of Wikipedia articles that belong to the category "Living People." We focus on this category because these articles are commonly updated: when new facts about a person are featured in the media, a corresponding entry in Wikipedia is likely to be modified. Unlike entries in a professionally edited encyclopedia, these articles are collaboratively written by multiple users, resulting in significant stylistic and content variations across texts in our corpus. This property distinguishes our corpus from more stylistically homogeneous collections of biographies used in text generation research (Duboue and McKeown, 2003).

We obtain data on insertions[6] from the update log that accompanies every Wikipedia entry. For each change in the article's history, the log records an article before and after the change. From this information, we can identify the location of every inserted sentence. In cases where multiple insertions occur over time to the same article, they are treated independently of each other. To eliminate spam, we place constraints on inserted sentences: (1) a sentence has at least 8 tokens and at most 120 tokens; (2) the MINIPAR parser (Lin, 1998) can identify a subject or an object in a sentence.

This process yields 4051 insertion/article pairs, from which 3240 pairs are used for training and 811 pairs for testing. These insertions are derived from 1503 Wikipedia articles. Relative to other corpora used in text structuring research (Barzilay and Lee, 2004; Lapata, 2003; Karamanis et al., 2004), texts in

[6] Insertion is only one type of recorded update, others include deletions and sentence rewriting.

our collection are long: an average article has 32.9 sentences, organized in 3.61 sections and 10.9 paragraphs. Our corpus only includes articles that have more than one section. When sentences are inserted between paragraphs, by convention we treat them as part of the previous paragraph.

Evaluation Measures We evaluate our model using *insertion accuracy* at the section and paragraph level. This measure computes the percentage of matches between the predicted location of the insertion and the true placement. We also report the *tree distance* between the predicted position and the true location of an inserted sentence. *Tree distance* is defined as the length of the path through the tree which connects the predicted and the true paragraph positions. This measure captures section level errors (which raise the connecting path higher up the tree) as well as paragraph level errors (which widen the path across the tree).

Baselines Our first three baselines correspond to naive insertion strategies. The RANDOMINS method randomly selects a paragraph for a new sentence, while FIRSTINS and LASTINS insert a sentence into the first and the last paragraph, respectively.

We also compare our HIERARCHICAL method against two competitive baselines, PIPELINE and FLAT. The PIPELINE method separately trains two rankers, one for section selection and one for paragraph selection. During decoding, the PIPELINE method first chooses the best section according to the section-layer ranker, and then selects the best paragraph within the chosen section according to the paragraph-layer ranker. The FLAT method uses the same decoding criterion as our model (Equation 2), thus making use of all the same features. However, FLAT is trained with the standard ranking perceptron update, without making use of the hierarchical decomposition of features in Equation 1.

Human Performance To estimate the difficulty of sentence insertion, we conducted experiments that evaluate human performance on the task. Four judges collectively processed 80 sentence/article pairs which were randomly extracted from the test set. Each insertion was processed by two annotators.

Table 1 shows the insertion accuracy for each judge when compared against the Wikipedia gold standard. On average, the annotators achieve 66% accuracy in section placement and 53% accuracy in paragraph placement. We obtain similar results when we compare the agreement of the judges against each other: 65% of section inserts and 48% of paragraph inserts are identical between two annotators. The degree of variability observed in this experiment is consistent with human performance on other text structuring tasks such as sentence ordering (Barzilay et al., 2002; Lapata, 2003).

	Section	Paragraph	Tree Dist
RANDOMINS	0.318*	0.134*	3.10*
FIRSTINS	0.250*	0.136*	3.23*
LASTINS	0.305*	0.215*	2.96*
PIPELINE	0.579	0.314*	2.21*
FLAT	0.593	0.313*	2.19*
HIERARCHY	**0.598**	**0.383**	**2.04**

Table 2: Accuracy of automatic insertion methods compared against the gold standard from Wikipedia's update log. The third column gives tree distance, where a lower score corresponds to better performance. Diacritic * ($p < 0.01$) indicates whether differences in accuracy between the given model and the Hierarchical model is significant (using a Fisher Sign Test).

6 Results

Table 2 shows the insertion performance of our model and the baselines in terms of accuracy and tree distance error. The two evaluation measures are consistent in that they yield roughly identical rankings of the systems. Assessment of statistical significance is performed using a Fisher Sign Test. We apply this test to compare the accuracy of the HIERARCHICAL model against each of the baselines.

The results in Table 2 indicate that the naive insertion baselines (RANDOMINS, FIRSTINS, LASTINS) fall substantially behind the more sophisticated, trainable strategies (PIPELINE, FLAT, HIERARCHICAL). Within the latter group, our HIERARCHICAL model slightly outperforms the others based on the coarse measure of accuracy at the section level. However, in the final paragraph-level analysis, the performance gain of our model over its counterparts is quite significant. Moreover, according to tree distance error, which incorporates error at both the section and the paragraph level, the performance of the

HIERARCHICAL method is clearly superior. This result confirms the benefit of our selective update mechanism as well as the overall importance of joint learning.

Viewing human performance as an upper bound for machine performance highlights the gains of our algorithm. We observe that the gap between our method and human performance at the paragraph level is 32% smaller than that between the PIPELINE model and human performance, as well as the FLAT model and human performance.

Sentence-level Evaluation Until this point, we have evaluated the accuracy of insertions at the paragraph level, remaining agnostic as to the specific placement within the predicted paragraph. We perform one final evaluation to test whether the global hierarchical view of our algorithm helps in determining the *exact* insertion point. To make sentence-level insertion decisions, we use a local model in line with previous sentence-ordering work (Lapata, 2003; Bollegala et al., 2006). This model examines the two surrounding sentences of each possible insertion point and extracts a feature vector that includes lexical, positional, and temporal properties. The model weights are trained using the standard ranking perceptron (Collins, 2002).

We apply this local insertion model in two different scenarios. In the first, we ignore the global hierarchical structure of the document and apply the local insertion model to every possible sentence pair. Using this strategy, we recover 24% of correct insertion points. The second strategy takes advantage of global document structure by first applying our hierarchical paragraph selection method and only then applying the local insertion to pairs of sentences within the selected paragraph. This approach yields 35% of the correct insertion points. This statistically significant difference in performance indicates that purely local methods are insufficient when applied to complete real-world documents.

7 Conclusion and Future Work

We have introduced the problem of sentence insertion and presented a novel corpus-based method for this task. The main contribution of our work is the incorporation of a rich hierarchical text representation into a flexible learning approach for text structuring. Our learning approach makes key use of the hierarchy by selecting to update only the layer found responsible for the incorrect prediction. Empirical tests on a large collection of real-world insertion data confirm the advantage of this approach.

Sentence ordering algorithms too are likely to benefit from a hierarchical representation of text. However, accounting for long-range discourse dependencies in the unconstrained ordering framework is challenging since these dependencies only appear when a particular ordering (or partial ordering) is considered. An appealing future direction lies in simultaneously inducing hierarchical and linear structure on the input sentences. In such a model, tree structure could be a hidden variable that is influenced by the observed linear order.

We are also interested in further developing our system for automatic update of Wikipedia pages. Currently, our system is trained on insertions in which the sentences of the original text are not modified. However, in some cases additional text revisions are required to guarantee coherence of the generated text. Further research is required to automatically identify and handle such complex insertions.

Abstract

In this paper we consider the problem of automatically identifying the arguments of discourse connectives (e.g., *and*, *because*, *nevertheless*) in the Penn Discourse TreeBank(PDTB). Rather than identifying the full *extents* of these arguments as annotated in the PDTB, however, we re-cast the problem to that of identifying the argument *heads*, effectively side-stepping the problem of *discourse segmentation*. We demonstrate significant gains using features derived from a dependency parse representation over those derived from a constituent-based tree parse. By also capturing inter-argument dependencies using a log-linear re-ranking model we identify both arguments correctly for over 74% of the connectives on held-out test data using gold-standard parses.

1 Introduction

The study of discourse is concerned with analyzing how phrase, clause or sentence-level units of text are *related* to each other within a larger unit of text (e.g., a document). Long recognized as important in dialog and text generation, this level of analysis is important generally for applications needing to place events and propositions in their proper context such as scenario-level information extraction, question answering, summarization, sentiment analysis and others.

In line with much of the NLP research agenda, recently a number of annotated corpora have emerged which encode discourse-level phenomena, making it possible to apply supervised, empirically-driven techniques to identifying discourse relations. Such corpora include the RST Discourse Treebank (Carlson et al., 2003) (based on Rhetorical Structure Theory), the Discourse GraphBank (Wolf and Gibson, 2005) (based on the relations of Hobbs (1985)) and the Penn Discourse Treebank (Miltsakaki et al., 2004b). While these corpora differ in many ways, they all more or less encode problems involving: 1) identifying/segmenting the basic units of discourse (e.g., clauses, phrases), 2) determining for which pairs of segments (or segment groups) a discourse relation exists, and 3) characterizing the *type* of relation (cause, elaboration, etc.) between segment pairs.

For our experiments in this paper, we use the Penn Discourse TreeBank (PDTB). The PDTB differs from most other discourse-level annotation efforts in its bottom-up, lexically-driven approach. Rather than identifying all possible discourse relations, the PDTB focuses on annotating relations lexicalized by discourse connectives that explicitly occur in the text along with their two arguments. [1] These discourse connectives include coordinating conjunctions (e.g., *and*, *or*), subordinating conjunctions (e.g., *because*, *when*, *since*) and discourse adverbials (e.g., *however*, *previously*, *nevertheless*).

In this paper we focus on problems (1) and (2)

[1] The final release of the PDTB, scheduled for release in August 2007, will annotate the *type* of the rhetorical relation holding between arguments of explicit connectives in addition to annotating relations between adjacent sentences where no lexical connective is present.

Proceedings of the 2007 Joint Conference on Empirical Methods in Natural Language Processing and Computational Natural Language Learning, pp. 92–101, Prague, June 2007. ©2007 Association for Computational Linguistics

above. However, rather than explicitly identifying the discourse segments and then deciding for which pairs a relation exists, we focus on identifying relations between the pairs of *head words* that *represent* the discourse segments. In this sense, the problem resembles that of predicate-argument identification where the predicates are discourse connectives and the arguments are single words which serve as anchors for the discourse segments.

To address the problem of identifying the arguments of discourse connectives we incorporate a variety of lexical and syntactic features in a discriminative log-linear ranking model. To capture dependencies between the two arguments of a connective we use a log-linear *re*-ranking model to select the best argument pair from a set of N-best argument pairs provided by the independent argument models. Further, we provide an analysis of the contribution of the various features demonstrating that features based on a dependency parse representation outperform features derived from a constituent tree parse.

2 Overview of the Penn Discourse Treebank

Discourse arguments in the PDTB represent abstract objects (Asher, 1993) which include facts, propositions and events. Each argument must include at least one predicate and can be realized as: a clause, a VP within VP coordination, a nominalization (in certain, restricted cases), an anaphoric expression or a response to a question. Each connective has two arguments: Arg2 is the argument syntactically connected to the connective in the same sentence and Arg1 is the other argument which may lie in the same sentence as the connective or, generally, anywhere prior in the discourse.

The PDTB contains a total of 18505 explicit connectives annotated with discourse arguments. The annotations are layered on top of the Penn TreeBank-II (PTB) parse trees and cover all 25 Wall Street Journal (WSJ) sections.

2.1 Examples

Below are a few examples from the PDTB. Each Arg1 is denoted in *italics* and each Arg2 is denoted in **bold**. The head-words for each argument are underlined. We discuss and motivate the identification of head-words in Section 2.2.

(1) *Choose 203 business executives, including, perhaps, someone from your own staff,* and **put them out on the streets**, to be deprived for one month of their homes, families and income.

(1) shows an example of a coordinating connective *and* and its two arguments. In this case, the Arg1 lies in the same sentence as the connective. It is also possible for the Arg1 to lie outside the sentence (usually in the immediately preceding sentence) when the coordinating connective begins a sentence.

An example of the subordinating connective, *because* is shown below in (2). This example brings up some interesting ambiguities that arise quite regularly in the data. An alternative reading for this example might only include the extent *to duck liability* for the Arg1. That is, the predicate *be able* could be read to include the discourse relation and its two arguments as an argument.

(2) *Drug makers shouldn't be able to duck liability* because **people couldn't identify precisely which identical drug was used.**

Both coordinating and subordinating connectives are *structural* (Webber et al., 2003). Discourse adverbials however, take one argument, Arg2, structurally but the other can be anaphoric: its Arg1 may be present anywhere in the current running discourse with little or no restriction. Example (3) shows the case in which the Arg1 lies in the previous sentence. In many cases, however, it resides in the same sentence as the connective or many sentences prior in the discourse.

(3) *France's second-largest government-owned insurance company, Assurances Generales de France, has been building its own Nagivation Mixte stake*, currently thought to be between 8% and 10%. Analysts said

they don't think it is contemplating a takeover, however, and its officials couldn't be reached.

2.2 Head-Based Representation of the PDTB

In contrast to other annotations layered on the PTB such as PropBank and NomBank, the arguments of a discourse connective generally do not correspond to a single parse tree constituent. Arguments consist instead of a *set* of non-overlapping constituents from the parse tree (i.e. a forest). This target representation makes the process of identifying the arguments to discourse connectives difficult since the space of candidate arguments extents is considerably larger than for PropBank parsing, for example. Even without this added difficulty, discourse segmentation is one of the most difficult stages in discourse parsing (Soricut and Marcu, 2003). While the segments themselves may be useful in certain contexts, for many applications, if not most, it will still be necessary to *interpret* these segments (e.g. at the predicate-argument level). As such, we argue that, in general, identifying the lexical *heads* of these discourse segments is sufficient and perhaps even preferable for this stage of processing. A problem arises, however, with arguments that consist of sequences of abstract objects represented as coordinated or subordinated sequences of VPs, clauses or sentences. What should the head be in such cases? By convention we designate the extent head as the head of the first element in the sequence. In (4), the head of the Arg2 would be *went*, but it's implicit scope includes the second VP coordinate headed by *caught*.

(4) Mr. Dozen even related *the indignity suffered* when **he and two colleagues went on an overnight fishing expedition of the New Jersey shore and caught nothing.**

The problem then becomes how to determine the end of the sequence of abstract objects. In many cases, there is a "natural end" to such sequences based on the syntax. In (4), the natural end is simply the end of the VP coordination. Difficult cases remain, however, particularly with multi-sentential Arg1s of anaphoric connectives. Determining the end of the these arguments seems non-trivial.[2] Nevertheless, identifying the begininning of the argument (via its head) is an important step in modeling these difficult cases.

2.3 Head Identification

Identifying the head of a discourse argument given its extent (as described by a set of constituent sub-trees in the PTB) consists of two steps. First, we construct a single syntactic tree formed by taking all of the sub-trees in the extent, finding their least common ancestor (LCA) node and including all intermediate nodes from the subtrees to the LCA node. Then, a slight variation of the head finding algorithm in (Collins, 1999) is applied to the derived tree to find the head. Figure 1 provides an example indicating the arguments to the connective "After" and the derived argument heads.

3 Discourse Argument Identification

Identifying the arguments of discourse connectives can be naturally formulated as a binary classification task where separate classifiers are trained for each argument — i.e., Arg1 and Arg2. First, a set of candidate arguments, α_i is gathered for each connective, π. Training instances, $\langle \alpha_i, \pi \rangle$, are then created for each candidate with respect to the connective. A training instance is positive if α_i is the true argument for π and negative otherwise. At decoding time, the candidate classified positively with the highest probability (or score) compared to the other candidates is selected as the argument.

An alternative to using a standard classification approach is to use a *ranking* model. The advantage of the ranking model is that candidate instances are compared against each other *during training* as well as during decoding. In

[2] There are indications, however, that the end of the argument sometimes falls out of the (possibly non-lexicalized) discourse relations local to the argument.

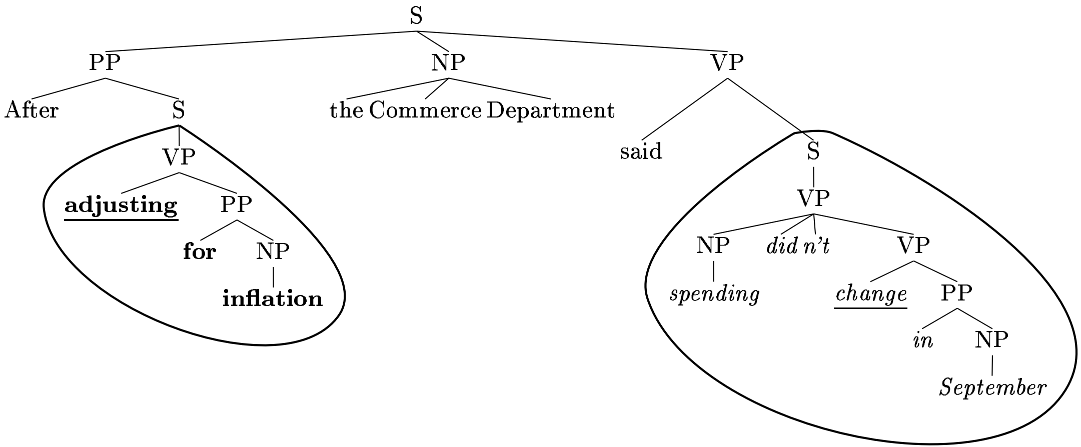

Figure 1: Syntactic structure and discourse arguments for the connective "After".

contrast, with a standard classifier, separate instances (i.e. candidates) are trained and classified as if they were completely independent. We use a log-linear ranking model. Such models have been used for a variety of other tasks including co-reference (Denis and Baldridge, 2007), question answering (Ravichandran et al., 2003) and parse re-ranking (Charniak and Johnson, 2005). For a given ARG1 candidate, α_i, the probability of that candidate being the argument given the connective, π, and the document, x, is defined according to the model as:

$$P_1(\alpha_i|\pi,x) = \frac{\exp\left(\sum_k \lambda_k f_k(\alpha_i,\pi,x)\right)}{\displaystyle\sum_{\alpha_j \in C_1(\pi,x)} \exp\left(\sum_k \lambda_k f_k(\alpha_j,\pi,x)\right)} \qquad (1)$$

where the f_k are feature functions, the λ_k are their weights and $C_1(\pi,x)$ is the set of candidate ARG1 arguments for the connective π in the document x. The model for ARG2 is defined analogously, but may in fact use a different set of features or a different candidate generation function. At training time, all potential candidates of a particular type for a given connective are provided to the ranking model as a distribution: the correct gold-standard candidate receiving a probability mass of 1.0 and the other candidates receiving masses of 0.0. During decoding, we select candidates in the same way as for training and produce a distribution over these candidates according to equation 1, selecting the candidate assigned the highest probability by the model as the argument.

We compared both the above ranking model and a standard binary Maximum Entropy model (i.e., logistic regression) and found the ranking model to have a small but consistent edge over the classifier. Accordingly, we only report results here using the ranking model.

3.1 Candidate Selection

Selecting the candidate arguments, α_i, is an important aspect of the problem. There are conceivably very many possible ARG1 candidates for a given connective stretching back from the sentence containing the connective to the beginning of the document. We employ two simple criteria to reduce the space of candidate argument head words. First, we only consider argument candidates that have an appropriate part-of-speech (all verbs, common nouns, adjectives). Second, we only consider candidates that are within 10 "steps" of the connective where a single step includes a sentence boundary or a syntactic dependency link within a sentence (see Figure 2). Only candidates lying within the same sentence as the connective are considered for ARG2.

3.2 Features

We used a variety of features for identifying the discourse arguments of a connective.

Baseline Features. Our baseline features included simply the connective and argument words, where the connective appears in the sentence, whether the argument precedes or follows the connective and whether the argument is in the same sentence as the connective or not.

Constituent Path Features. As noted in work on semantic role labeling, features derived from the constituent parse of the sentence can be very helpful for deriving the argument structure of predicating verbs (Toutanova et al., 2005) and nouns (Jiang and Ng, 2006). Syntax plays a strong role in identifying discourse arguments, too, though even for structural connectives it by no means "aligns" with the discourse structure (Dinesh et al., 2005). We introduced a feature capturing the constituent tree path from the connective to the candidate argument as well as variants in which repeated nodes and part-of-speech nodes are removed from the path. If the argument lies in a different sentence, the path from the connective to the argument consists of the path from the connective to the top node of its sentence, followed by a series of virtual *SENT* nodes for the intervening sentences and then ending with the path from the top node of the sentence containing the argument to the argument head itself.

Dependency Path Features. We experimented with a number of syntactic features based on a *dependency* parse representation. The primary motivation here being that it provides for a more compact and natural representation of the syntax, providing for better syntactic features with less data sparseness than constituent path features. The dependency representation we use is that put forth in de Marneffe et al. (2006) and we apply their approach to deriving the dependency structure from the constituent parse. The features used here include the (shortest) dependency path from the connective to the prospective argument and two collapsed versions removing coordination links as well as repeated links of the same type. For argument candidates in prior sentences, we introduce *SENT* links for each intervening sentence.

Connective Features. Different discourse connectives behave differently depending on their type. A potentially important feature then involves capturing the connective type: (coordinating, subordinating or adverbial). We use the categorized lists of discourse connectives found in (Knott, 1996); further, any connectives not appearing in these lists are considered discourse adverbials. As we would expect different syntax associated with different connectives we introduce conjunctive features such as the connective type and syntactic path.

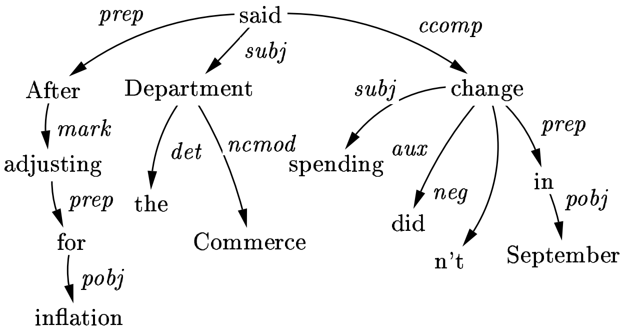

Figure 2: Dependency structure.

Lexico-Syntactic Features. One of the prime difficulties in identifying the correct non-anaphoric argument has to do with *attribution.* In this situation the argument is the complement of a verb indicating attribution of the proposition denoted by the complement to an individual other than the writer. Figure 1 provides an example of this where the ARG1 of "After" is the complement of the verb "said" being attributed to "the Commerce Department". To model this situation we introduce features capturing whether the argument is a potentially attribution-denoting verb, whether it has a clausal complement, whether it is the clausal complement of another verb and whether the complementing verb is attributing.

A full listing of the features used for identifying arguments is shown in Table 1.

4 Experiments with Independent Argument Identification

For all of our experiments, we use sections 02-22 for training, sections 00-01 for development and sections 23-24 for testing. The development data was used to customize our features and to tune the Gaussian prior used to prevent over-

Baseline Features	
A	Where in the sentence (beginning, middle, end) the connective resides
B	Whether the argument is in the same sentence as the connective (yes,no)
C	Connective phrase
D	Downcase connective phrase
E	Argument head word
F	Argument head prior or after connective
G	A & B
Constitutent Features	
H	Path from argument to connective through the constituent tree
I	Length of path
J	Collapsed path without part-of-speech
K	Collapsed path removing repetitions of the same node type (e.g. VP-VP-VP → VP)
L	C & H
Dependency Features	
M	Dependency path from argument to connective
N	Path + head word of first link from connective
O	Collapsed path removing coordinating links
P	Collapsed path removing repetitions of links
Q	C & M
Connective Features	
R	coordinating, subordinating or adverbial connective
S	A & R
T	M & R
Lexico-Syntactic Features	
U	Argument is an attributing verb
V	Argument has a clausal complement
W	U & V
X	Argument is a clausal complement of a verb
Y	X & governing verb is an attributing verb

Table 1: Feature types for discourse connective argument identification

fitting in the log-linear models (at $\sigma = 0.25$ for both the local and the re-ranking models). All results are reported on the testing data, sections 23-24. We report results using both gold-standard parses and automatic parses using the Charniak-Johnson parser (Charniak and Johnson, 2005).

For evaluating Arg1 and Arg2 argument identification performance we report *accuracy* — i.e., the percentage of arguments correctly identified. An argument is correct if and only if it is the same head-word as derived from the argument extent as annotated in the PDTB (as described in Section 2.3). We also report *Connective Accuracy* which is the percentage of connectives for which *both* arguments were correctly identified.

	Accuracy		
FeatureSet	Arg1	Arg2	Conn.
A-G	32.7	60.7	21.6
A-L	60.6	85.5	53.6
A-G;M-Q	73.7	94.2	70.2
A-Y	75.0	94.2	71.7
A-Y(auto)	67.9	90.6	62.7

Table 2: Results for argument identification on the testing data (WSJ sections 23-24) gold standard parses (with various feature sets) and Charniak-Johnson parses (auto) for the full feature set A-Y.

Our results for the task of identifying arguments are shown in Table 4 for various feature combinations. It is interesting to compare the performance of the constituent parse features (A-L) vs. the dependency parse features (A-G;M-Q). The dependency parse features perform markedly better: 70.2 vs. 53.6 Connective Accuracy with gold-standard parses.

5 Experiments With Re-ranking

A drawback to the above approach is that the two arguments are identified independently. Ideally, one would like to consider both arguments and the connective simultaneously, taking into account global properties such as the pattern of the argument structure (e.g. Connective-Arg2-Arg1 vs. Arg1 Connective Arg2) or properties of compatibility between the two arguments (e.g. agreement in tense). Considering all pairs of arguments outright, however, presents scalability issues as the number of such pairs can be very large (especially with anaphoric Arg1s). Indeed, a huge advantage of the lexicalized approach taken with the PDTB is that we *can* identify arguments independently using the connectives as anchors. Nevertheless, there is obvious potential gain from modeling pairs of arguments jointly.

One way to model these dependencies in a tractable fashion is to use a *re-ranking* approache (Collins, 2000) which has proven successful in a variety of NLP tasks. The basic idea is to use a model with strong independenc as-

	Accuracy		
N	ARG1	ARG2	Conn.
1	74.5	94.5	71.4
5	83.1	97.4	81.8
10	90.5	97.9	89.2
20	93.8	97.9	92.1
30	94.6	97.9	92.9

Table 3: N-best upper-bounds for different values of N according to a product of independent argument ranker probabilities with the full feature set (A-Y)

sumption, $GEN(\pi)$, in this case based on the independent argument models described above, to generate N candidate argument pairs for a given connective, π. Then, the re-ranking model is used to re-rank these candidate pairs; the top-ranked pair is then selected.

In our setting for a given connective, π, we define the *local probability* for a candidate argument pair, $\langle\alpha_i, \alpha_j\rangle$ as:

$$P_{loc}(\alpha_i, \alpha_j|\pi, x) = P_{\text{ARG1}}(\alpha_i|\pi, x)\cdot P_{\text{ARG2}}(\alpha_j|\pi, x)$$

Thus, $GEN(\pi)$ generates the top N argument pairs according to the P_{loc}. In practice, we also assert that $P_{loc}(\alpha_j, \alpha_k|\pi, x) = 0$ when $j = k$.

For different values of N, Table 3 shows the oracle upper bounds on performance - the performance achieved by selecting the correct argument pair from $GEN(\pi)$ if it is in the list of argument pairs and otherwise selecting the first pair with one correct argument if such a pair exists. Note that performance on ARG2 plateaus at 97.9. This is due to 2.1 percent of the ARG2s not being reachable because they are not considered candidates (they are more than 10 “parse steps” away or an invalid part-of-speech).

5.1 Modeling Inter-Argument Dependencies

The model for re-ranking pairs of arguments is given by

$$P_r(\alpha_i, \alpha_j|\pi, x) = \frac{\exp\left(\sum_k \lambda_k f_k(\alpha_i, \alpha_j, \pi, x)\right)}{\sum_{\alpha_i, \alpha_j \in GEN(\pi)} \exp\left(\sum_k \lambda_k f_k(\alpha_i, \alpha_j, \pi, x)\right)}$$

Following previous work (Collins, 2000; Toutanova et al., 2005), we mix the local model into the final score along with the re-ranking model as:

$$P(\alpha_i, \alpha_j|\pi, x) = P_{loc}(\alpha_i, \alpha_j|\pi, x)^{\gamma}\cdot P_r(\alpha_i, \alpha_j|\pi, x)$$

where γ indicates the degree to which the local model influences the final score. Tuning γ on the development data, we set $\gamma = 0.4$ for all our re-ranking experiments.

The re-ranking model is able to accommodate features over *both* candidate arguments. For example, we can test whether the two arguments are the same predicate or whether they are both reporting verbs. Another set of features consists of triples denoting the relative order of the arguments and the connective. For example, the feature *CONN*_ARG2_ARG1 indicates the connective and both arguments lie in the same sentence with the connective first, followed by ARG2 and then ARG1. The feature *Prev_CONN*_ARG2 indicates ARG1 is in the previous sentence and the connective precedes ARG2 within the sentence containing the connective. Other slight variations capture configurations where the ARG1 candidate lies further back in the discourse. Finally, we found some utility in comparing the syntactic arguments (e.g., subject, direct object) of the candidate argument pairs. For example, the arguments of the discourse adverbial *also* not only frequently involve the same predicate but also involve the same entities that appear as arguments to the predicate. Currently, we simply introduce features testing whether the argument strings are identitical as a proxy for full co-reference.

Table 4 shows the results incorporating the re-ranking model for the different feature sets described earlier. The re-ranking models in each case are constructed from the features that would naturally be available to the re-ranker. For example, the re-ranking model for feature set A-Y uses a feature testing whether both candidate arguments are reporting verbs, whereas the re-ranking model for A-L doesn’t.

	Accuracy			
Features	Arg1	Arg2	Conn.	Err.
A-G	44.1	59.6	30.6	11.5%
A-L	64.7	85.6	58.1	9.6%
A-G;M-Q	74.2	94.4	71.8	5.4%
A-Y	76.4	95.4	74.2	8.8%
A-Y(auto)	69.8	90.8	64.6	5.4%

Table 4: Re-ranking results for argument identification on the testing data using gold-standard and Charniak-Johnson parses for the full feature set, A-Y (auto). The error reduction (Err.) is relative to the results in Table 2.

5.2 Discussion and Error Analysis

Not surprisingly, performance at identifying Arg2s is much higher than for Arg1s as the former are syntactically bound to the connective. Indeed, performance for identifying Arg2s may be at or very close to human levels of performance using gold-standard parses. Miltsakaki et al. (2004a) indicate 94.1% inter-annotator agreement for Arg2, 86.3% on Arg1 and 82.8% agreement per discourse connective with respect to the full argument extents for a set of 10 connectives. The disagreement rates, however, would likely be reduced considerably using our head-based representation since almost half of the disagreements reported were due to argument extent disagreements.

Many of the Arg2 errors we found had to do with attribution, such as:

(5) ..“We pretty much *have* a policy of not commenting on rumors, and I **think(?)** that **falls** in that category.

where the system proposed “think” as the Arg2 and the annotated argument was “falls”.

The Arg1 errors were much more diverse with many involving arguments in previous sentences, such as the following case in which the system proposed *owned* as the argument yet the correct argument was *completed* found three sentences prior in the discourse.

(6) ..Quantum *completed* in August an acquisition of Petrolane... Petrolane is the second-largest... The largest, Suburban Propane, was already *owned(?)* by Quantum. Still, Quantum **has** a crisis to get past right now.

Conn. Type	Freq.	Indep. Acc.	Rerank Acc.	Err.
Coord.	662	75.5	78.3	11.4%
Subord.	547	87.2	86.8	-3.0%
Adv.	386	42.2	49.0	11.8%
Total	1595	71.7	74.2	8.8%

Table 5: Frequency of each connective type and connective accuracy for the independent and re-ranking approaches using gold-standard parses and features (A-Y).

An examination of the errors by connective type is shown in Table 5. The re-ranking model provides considerable improvement for coordinating and adverbial connectives, but slighly *lowers* performance for subordinating connectives. Overall performance on discourse adverbials remains below 50% however.

6 Related Work

Given the formulation of discourse relations as predicate-argument structures anchored on discourse connectives, our work here bears some resemblance to work in semantic role labeling that has focused on identifying semantic frames for verbs (Toutanova et al., 2005). The task of identifying discourse relations is simpler in that there are only and exactly two arguments for each predicate; yet it is more difficult due to many more candidate arguments not contained within a single sentence.

Within discourse parsing, our work is similar to that of Soricut and Marcu (2003) but they focus only on identifying (and labeling the type of) all intra-sentential discourse relations whereas we attempt to identify discourse relations spanning multiple sentences, provided they are lexicalized by a connective. While not directly comparable to our results, they report 73.0 F-measure at identifying intra-sentential discourse relations and segments using gold-standard parses. With gold-standard discourse segments provided, their system achieves human-levels of performance (96.2

F-measure), broadly comparable to our near-human levels of performance on identifying Arg2s with gold-standard parses. Sporleder and Lapata (2005) address intra-sentential discourse modeling with a chunking approach. They achieve 88.7 F-measure on identifying discourse segment boundaries and 76.3 F-measure when also labeling each segment as a nucleus or satellite. Webber et al. (2003) provide a discourse parsing model, DLTAG, which is an extension of Lexicalized Tree Adjoining Grammars. Baldridge and Lascarides (2005) present a discourse parser for dialogue in the framework of SDRT (Asher, 1993) and achieve 67.9 F-measure on identifying and segmenting discourse relations.

7 Conclusions and Future Work

We have presented a fully automated system capable of identifying the arguments of discourse connectives. Rather than identifying the full argument extents in the PDTB, we have proposed here an alternative problem formulation: that of identifying the heads of discourse arguments. [3] With such a representation our system achieves 74.2% accuracy using gold-standard parses and 64.6% accuracy using automatic parses on the task of correctly identifying both arguments of discourse connectives. We found that syntactic features based on a dependency parse representation provide more discriminative features over those based on a constituent tree representation. Additionally, we found a notable improvement by exploiting joint features over argument pairs in a re-ranking model in comparison to modeling the arguments independently.

We have provided here, to our knowledge, the first rigorous empirical results on identifying the arguments of discourse connectives in the PDTB. Accordingly, many avenues remain for future work. Further feature engineering, particularly work capturing the lexico-semantic, attributive and predicate-argument properites of arguments appears necessary to better identify the Arg1s of anaphoric discourse adverbials, in particular. Introducing separate models and feature sets for each of the three connective types may also prove beneficial since phenomena involved vary according to connective type.

While we have demonstrated some encouraging results by modeling both arguments jointly, we hypothesize more gains are possible by modeling *inter-connective* dependencies. The discourse arguments of one connective are not independent of other (nearby) connectives and their arguments. For example, it is very rare to see crossing argument links. Capturing these inter-connective dependencies and constraints is likely to be even more important when considering the task of identifying the rhetorical *types* associated with the connectives or when considering non-lexicalized relations between adjacent sentences.

Finally, jointly modeling PropBank and the PDTB is another interesting area we plan to investigate, something to which the head-based approach and dependency parse representation we advocate here would be well-suited.

Incremental generation of plural descriptions: Similarity and partitioning

Albert Gatt and **Kees van Deemter**
Department of Computing Science
University of Aberdeen
{agatt,kvdeemte}@csd.abdn.ac.uk

Abstract

Approaches to plural reference generation emphasise descriptive brevity, but often lack empirical backing. This paper describes a corpus-based study of plural descriptions, and proposes a psycholinguistically-motivated algorithm for plural reference generation. The descriptive strategy is based on partitioning and incorporates corpus-derived heuristics. An exhaustive evaluation shows that the output closely matches human data.

1 Introduction

Generation of Referring Expressions (GRE) is a well-studied sub-task of microplanning in Natural Language Generation. Most algorithms in this area view GRE as a content determination problem, that is, their emphasis is on the construction of a semantic representation which is eventually mapped to a linguistic realisation (i.e. a noun phrase). Content Determination for GRE starts from a Knowledge Base (KB) consisting of a set of entities U and a set of properties $\mathbb{P}$ represented as attribute-value pairs, and searches for a description $D \subseteq \mathbb{P}$ which distinguishes a referent $r \in U$ from its distractors. Under this view, reference is mainly about *identification* of an entitiy in a given context (represented by the KB), a well-studied pragmatic function of definite noun phrases in both the psycholinguistic and the computational literature (Olson, 1970).

For example, the KB in Table 1 represents 8 entities in a $2D$ visual domain, each with 6 attributes, including their location, represented as a combination of horizontal (X) and vertical (Y) numerical coordinates. To refer to an entity an algorithm searches through values of the different attributes.

	TYPE	COLOUR	ORIENTATION	SIZE	X	Y
e_1	desk	red	back	small	3	1
e_2	sofa	blue	back	small	5	2
e_3	desk	red	back	large	1	1
e_4	desk	red	front	large	2	3
e_5	desk	blue	right	large	2	4
e_6	sofa	red	back	large	4	1
e_7	sofa	red	front	large	3	3
e_8	sofa	blue	back	large	3	2

Table 1: A visual domain

GRE has been dominated by Dale and Reiter's (1995) Incremental Algorithm (IA), one version of which, generalised to deal with *non-disjunctive* plural references, is shown in Algorithm 1 (van Deemter, 2002). A non-disjunctive reference to a set R is possible just in case all the elements of R can be distinguished using the same attribute-value pairs. Such a description is equivalent to the logical conjunction of the properties in question. This algorithm, IA$_{plur}$, initialises a description D and a set of distractors C [1.1–1.2], and traverses an ordered list of properties, called the *preference order* ($\mathcal{PO}$) [1.3], which reflects general or domain-specific pref-

Algorithm 1 IA$_{plur}$(R,U,$\mathcal{PO}$

```
1:  $D \leftarrow \emptyset$
2:  $C \leftarrow U - R$
3:  for $\langle A : v \rangle \in \mathcal{PO}$ do
4:      if $R \subseteq \llbracket \langle A : v \rangle \rrbracket \wedge \llbracket \langle A : v \rangle \rrbracket - C \neq \emptyset$ then
5:          $D \leftarrow D \cup \{\langle A : v \rangle\}$
6:          $C \leftarrow C \cap \llbracket \langle A : v \rangle \rrbracket$
7:          if $\llbracket D \rrbracket = R$ then
8:              return $D$
9:          end if
10:     end if
11: end for
12: return $D$
```

Proceedings of the 2007 Joint Conference on Empirical Methods in Natural Language Processing and Computational Natural Language Learning, pp. 102–111, Prague, June 2007. ©2007 Association for Computational Linguistics

erences for attributes. For instance, with the $\mathcal{PO}$ in the top row of the Table, the algorithm first considers values of TYPE, then COLOUR, and so on, adding a property to D if it is true of the intended referents R, and has some *contrastive value*, that is, excludes some distractors [1.4]. The description and the distractor set C are updated accordingly [1.5–1.6], and the description returned if it is distinguishing [1.7]. Given $R = \{e_1, e_2\}$, this algorithm would return the following description:

(1) $\langle$ORIENTATION : *back*$\rangle \wedge \langle$SIZE : *small*$\rangle$

This description is overspecified, because ORIENTATION is not strictly necessary to distinguish the referents ($\langle$SIZE : *small*$\rangle$ suffices). Moreover, the description does not include TYPE, though it has been argued that this is always required, as it maps to the head noun of an NP (Dale and Reiter, 1995). We will adopt this assumption here, for reasons explained below. Due to its hillclimbing nature, the IA avoids combinatorial search, unlike some predecessors which searched exhaustively for the briefest possible description of a referent (Dale, 1989), based on a strict interpretation of the Gricean Maxim of Quantity (Grice, 1975). Given that, under the view proposed by Olson (1970) among others, the function of a referential NP is to identify, a strict Gricean interpretation holds that it should contain no more information than necessary to achieve this goal.

The Incremental Algorithm constitutes a departure from this view given that it can overspecify through its use of a $\mathcal{PO}$. This has been justified on psycholinguistic grounds. Speakers overspecify their descriptions because they begin their formulation of a reference without exhaustively scanning a domain (Pechmann, 1989; Belke and Meyer, 2002). They prioritise the basic-level category (TYPE) of an object, and salient, absolute properties like COLOUR (Pechmann, 1989; Eikmeyer and Ahlsèn, 1996), as well as locative properties in the vertical dimension (Arts, 2004). Relative attributes like SIZE are avoided unless absolutely required for identification (Belke and Meyer, 2002). This evidence suggests that speakers conceptualise referents as *gestalts* (Pechmann, 1989) whose core is their basic-level TYPE (Murphy, 2002) and some other salient attributes like COLOUR. For instance, according to Schriefers and Pechmann (1988), an NP such as *the large black triangle* reflects a conceptualisation of the referent as a *black triangle*, of which the SIZE property is predicated. Thus, the TYPE+COLOUR combination is not mentally represented as two separable dimensions.

In what follows, we will sometimes refer to this principle as the *Conceptual Gestalts Principle*. Note that the IA does not fully mirror these human tendencies, since it only includes preferred attributes in a description if they remove some distractors given the current state of the algorithm, whereas psycholinguistic research suggests that people include them irrespective of contrastiveness (but cf. van der Sluis and Krahmer (2005)).

More recent research on plural GRE has de-emphasised these issues, especially in case of *disjunctive* plural reference. Disjunction is required whenever elements of a set of referents R do not have identical distinguishing properties. For example, $\{e_1, e_3\}$ can be distinguished by the following Conjunctive Normal Form (CNF) description[1]:

(2) $\langle$TYPE : *desk*$\rangle \wedge \big(\langle$COLOUR : *red*$\rangle \vee \langle$COLOUR : *blue*$\rangle\big) \wedge \big(\langle$ORIENTATION : *right*$\rangle \vee \langle$ORIENTATION : *back*$\rangle\big)$

Such a description would be returned by a generalised version of Algorithm 1 proposed by van Deemter (2002). This generalisation, IA$_{bool}$ (so called because it handles all Boolean operators, such as negation and disjunction), first tries to find a non-disjunctive description using Algorithm 1. Failing this, it searches through disjunctions of properties of increasing length, conjoining them to the description. This procedure has three consequences:

1. **Efficiency**: Searching through disjunctive combinations results in a combinatorial explosion (van Deemter, 2002).

2. **Gestalts and content**: The notion of a 'preferred attribute' is obscured, since it is difficult to apply the same reasoning that motivated the $\mathcal{PO}$ in the IA to combinations like (COLOUR $\vee$ SIZE).

[1] Note that logical disjunction is usually rendered as linguistic coordination using *and*. Thus, *the table and the desk* is the union of things which are desks *or* tables.

3. **Form**: Descriptions can become logically very complex (Gardent, 2002; Horacek, 2004).

Proposals to deal with (3) include Gardent's (2002) non-incremental, constraint-based algorithm to generate the briefest available description of a set, an approach extended in Gardent et al. (2004). An alternative, by Horacek (2004), combines best-first search with optimisation to reduce logical complexity. Neither approach benefits from empirical grounding, and both leave open the question of whether previous psycholinguistic research on singular reference is applicable to plurals.

This paper reports a corpus-based analysis of plural descriptions elicited in well-defined domains, of which Table 1 is an example. This study falls within a recent trend in which empirical issues in GRE have begun to be tackled (Gupta and Stent, 2005; Jordan and Walker, 2005; Viethen and Dale, 2006). We then propose an efficient algorithm for the generation of references to arbitrary sets, which combines corpus-derived heuristics and a partitioning-based procedure, comparing this to IA$_{bool}$. Unlike van Deemter (2002), we only focus on disjunction, leaving negation aside. Our starting point is the assumption that plurals, like singulars, evince preferences for certain attributes as predicted by the Conceptual Gestalts Principle. Based on previous work in Gestalt perception (Wertheimer, 1938; Rock, 1983), we propose an extension of this to sets, whereby plural descriptions are preferred if (a) *they maximise the similarity of their referents*, using the same attributes to describe them as far as possible; (b) prioritise salient ('preferred') attributes which are central to the conceptual representation of an object. We address (3) above by investigating the logical form of plurals in the corpus. One determinant of logical form is the basic-level category of objects. For example, to refer to $\{e_1, e_2\}$ in the Table, an author has at least the following options:

(3) (a) the small desk and sofa
(b) the small red desk and the small blue sofa
(c) the small desk and the small blue sofa
(d) the small objects

These descriptions exemplify three possible sources of variation:

Disjunctive/Non-disjunctive: The last description, (3d), is non-disjunctive (i.e. it is logically a conjunction of properties). This, however, is only achievable through the use of a non-basic level value for the TYPE of the entities (*objects*). Using the basic-level would require the disjunction ($\langle$TYPE : *desk*$\rangle \vee \langle$TYPE : *sofa*$\rangle$), which is the case in (3a–c). Given that basic-level categories are preferred on independent grounds (Rosch et al., 1976), we would expect examples like (3d) to be relatively infrequent.

Aggregation: If a description is disjunctive, it may be aggregated, with properties common to all objects realised as wide-scope modifiers. For instance, in (3a), *small* modifies *desk and sofa*. By contrast, (3b) is *non-aggregated*: *small* occurs twice (modifying each coordinate in the NP). Non-aggregated, disjunctive descriptions are logically equivalent to a partition of a set. For instance, (3c) partitions the set $R = \{e_1, e_2\}$ into $\{\{e_1\}, \{e_2\}\}$, describing each element separately. Descriptions like (3b) are more overspecified than their aggregated counterparts due to the repetition of information.

Paralellism/Similarity: Non-aggregated, disjunctive descriptions (partitions) may exhibit *semantic parallelism*: In (3b), elements of the partition are described using exactly the same attributes (that is, TYPE, COLOUR, and SIZE). This is not the case in (3c), which does represent a partition but is *non-parallel*. Parallel structures maximise the similarity of elements of a partition, using the same attributes to describe both. The likelihood of propagation of an attribute across disjuncts is probably dependent on its degree of salience or preference (e.g. COLOUR is expected to be more likely to be found in a parallel structure than SIZE).

2 The data

The data for our study is a subset of the TUNA Corpus (Gatt et al., 2007), consisting of 900 references to furniture and household items, collected via a controlled experiment involving 45 participants. In addition to their TYPE, objects in the domains have COLOUR, ORIENTATION and SIZE (see Table 1). For each subset of these three attributes, there was an equal number of domains in which the minimally distinguishing description (MD) consisted of values of that subset. For example, Table 1 represents a domain in which the intended referents, $\{e_1, e_2\}$, can

```
<DESCRIPTION num='pl'>
<DESCRIPTION num='sg'>
<ATTRIBUTE name='size' value='small'>small</ATTRIBUTE>
<ATTRIBUTE name='colour' value='red'>red</ATTRIBUTE>
<ATTRIBUTE name='type' value='desk'>desk</ATTRIBUTE>
</DESCRIPTION>
and
<DESCRIPTION num='sg'>
<ATTRIBUTE name='size' value='small'>small</ATTRIBUTE>
<ATTRIBUTE name='colour' value='blue'>blue</ATTRIBUTE>
<ATTRIBUTE name='type' value='sofa'>sofa</ATTRIBUTE>
</DESCRIPTION>
</DESCRIPTION>
```

$$(\langle \textsc{size} : \mathit{small}\rangle \wedge \langle \textsc{colour} : \mathit{red}\rangle \wedge \langle \textsc{type} : \mathit{desk}\rangle) \\ \vee \\ (\langle \textsc{size} : \mathit{small}\rangle \wedge \langle \textsc{colour} : \mathit{blue}\rangle \wedge \langle \textsc{type} : \mathit{sofa}\rangle)$$

Figure 1: Corpus annotation examples

be minimally distinguished using only SIZE[2]. Thus, overspecified usage of attributes can be identified in authors' descriptions. Domain objects were randomly placed in a 3 (row) × 5 (column) grid, represented by X and Y in Table 1. These are relevant for a subset of descriptions which contain locative expressions.

Corpus descriptions are paired with an explicit XML domain representation, and annotated with semantic markup which makes clear which attributes a description contains. This markup abstracts away from differences in lexicalisation, making it an ideal resource to evaluate content determination algorithms, because it is *semantically transparent*, in the sense of this term used by van Deemter et al. (2006). This markup scheme also enables the compositional derivation of a logical form from a natural language description. For example, the XML representation of (3b) is shown in Figure 1, which also displays the LF derived from it. Each constituent NP in (3b) is annotated as a set of attributes enclosed by a DESCRIPTION tag, which is marked up as singular (sg). The two coordinates are further enclosed in a plural DESCRIPTION; correspondingly, the LF is a disjunction of (the LFs of) the two internal descriptions.

Descriptions in the corpus were elicited in 7 domains with one referent, and 13 domains with 2 referents. Plural domains represented levels of a *Value Similarity* factor. In 7 *Value-Similar* (VS) domains, referents were identifiable using identical values of the minimally distinguishing attributes. In the remaining 6 *Value-Dissimilar* (VDS) domains, the minimally distinguishing values were different. Table 1 represents a VS domain, where $\{e_1, e_2\}$ can be minimally distinguished using the same value of SIZE (*small*).

	VS		VDS	
	+Disj	−Disj	+Disj	−Disj
+aggr	20.2	15.5	2.4	3.7
−aggr	64.3	–	93.9	–
% overall	84.5	15.5	96.3	3.7

Table 2: % disjunctive and non-disjunctive plurals

In terms of our introductory discussion, referents in *Value-Similar* conditions could be minimally distinguished using a conjunction of properties, while *Value-Dissimilar* referents required a disjunction since, if two referents could be minimally distinguished by different values v and v' of an attribute A, then MD had the form $\langle \textsc{a} : v\rangle \vee \langle \textsc{a} : v'\rangle$. However, even in the VS condition, referents had different basic-level types. Thus, an author faced with a domain like Table 1 had at least the descriptive options in (3a–d). If they chose to refer to entities using basic-level values of TYPE, their description would be disjunctive (e.g. 3a). A non-disjunctive description would require the use of a superordinate value, as in (3d).

Our analysis will focus on a stratified random sample of 180 plural descriptions, referred to as $\textsc{pl}_1$, generated by taking 4 descriptions from each author (2 each from VS and VDS conditions). We also use the singular data (SG; $N = 315$). The remaining plural descriptions ($\textsc{pl}_2$; $N = 405$) are used for evaluation.

3 The logical form of plurals

Descriptions in $\textsc{pl}_1$ were first classified according to whether they were non-disjunctive (cf. 3d) or disjunctive (3a–c). The latter were further classified into aggregated (3a) and non-aggregated (3b). Table 2 displays the percentage of descriptions in each of the four categories, within each level of Value Similarity. Disjunctive descriptions were a majority in either condition, and most of these were non-aggregated. As noted in §1, these descriptions correspond to partitions of the set of referents.

Since referents in VS had identical properties except for TYPE values, the most likely reason for the majority of disjunctives in VS is that people's descriptions represented a partition of a set of referents induced by the basic-level category of the ob-

[2] TYPE was not included in the calculation of MD.

	Non-Parallel	Parallel	χ^2 ($p \leq .001$)
overspec.	24.6	75.4	92.467
underspec.	5.3	94.7	42.217
well-spec.	11	89	26

Table 3: Parallelism: % per description type

	Actual		Predicted
	$p(\text{A}, \text{SG})$	$p(\text{A}, \text{PPS})$	$p(\text{A}, \text{PPS})$
COLOUR	.680	.835	.61
SIZE	.290	.359	.28
ORIENTATION	.280	.269	.26
X-DIMENSION	.440	.517	.52
Y-DIMENSION	.630	.647	.65

Table 4: Actual and predicted usage probabilities

jects. This is strengthened by the finding that the likelihood of a description being disjunctive or non-disjunctive did not differ as a function of Value Similarity ($\chi^2 = 2.56$, $p > .1$). A χ^2 test on overall frequencies of aggregated versus non-aggregated disjunctives showed that the non-aggregated descriptions ('true' partitions) were a significant majority ($\chi^2 = 83.63$, $p < .001$). However, the greater frequency of aggregation in VS compared to VDS turned out to be significant ($\chi^2 = 15.498$, $p < .001$). Note that the predominance of non-aggregated descriptions in VS implies that properties are repeated in two disjuncts (resp. coordinate NPs), suggesting that authors are likely to redundantly propagate properties across disjuncts. This evidence goes against some recent proposals for plural reference generation which emphasise brevity (Gardent, 2002).

3.1 Conceptual gestalts and similarity

Allowing for the independent motivation for set partitioning based on TYPE values, we suggested in §1 that *parallel* descriptions such as (3b) may be more likely than *non-parallel* ones (3c), since the latter does not use the same properties to describe the two referents. Similarity, however, should also interact with attribute preferences.

For this part of the analysis, we focus exclusively on the disjunctive descriptions in PL$_1$ ($N = 150$) in both VS and VDS. The descriptions were categorised according to whether they had *parallel* or *non-parallel* semantic structure. Evidence for Similarity interacting with attribute preferences is strongest if it is found in those cases where an attribute is overspecified (i.e. used when not required for a distinguishing description). In those cases where corpus descriptions do not contain locative expressions (the X and/or Y attributes), such an overspecified usage is straightforwardly identified based on the MD of a domain. This is less straightforward in the case of locatives, since the position of objects was randomly determined in each domain. Therefore, we divided descriptions into three classes, whereby a description is considered to be:

1. *underspecified* if it does not include a locative expression and omits some MD attributes;
2. *overspecified* if either (a) it does not omit any MD attributes, but includes locatives and/or non-required visual attributes; or (b) it omits some MD attributes, but includes both a locative expression and other, non-required attributes;
3. *well-specified* otherwise.

Proportions of Parallel and Non-Parallel descriptions for each of the three classes are are shown in Table 3. In all three description types, there is an overwhelming majority of Parallel descriptions, confirmed by a χ^2 analysis. The difference in proportions of description types did not differ between VS and VDS ($\chi^2 < 1$, $p > .8$), suggesting that the tendency to redundantly repeat attributes, avoiding aggregation, is independent of whether elements of a set can be minimally distinguished using identical values.

Our second prediction was that the likelihood with which an attribute is used in a parallel structure is a function of its overall 'preference'. Thus, we expect attributes such as COLOUR to feature more than once (perhaps redundantly) in a parallel description to a greater extent than SIZE. To test this, we used the SG sample, estimating the overall probability of occurrence of a given attribute in a singular description (denoted $p(\text{A}, \text{SG})$), and using this in a non-linear regression model to predict the likelihood of usage of an attribute in a plural partitioned description with parallel semantic structure (denoted $p(\text{A}, \text{PPS})$). The data was fitted to a regression equation of the form $p(\text{A}, \text{PPS}) = k \times p(\text{A}, \text{SG})^S$. The resulting equation, shown in (4), had a near-perfect fit to the data ($R^2 = .910$)[3]. This is confirmed by comparing actual probability of occurrence in the second column of Table 4, to the predicted probabilities in the third column, which are estimated from singular probabilities using (4).

$$p(\textsc{a}, \textsc{pps}) = .713\, p(\textsc{a}, \textsc{sg})^{.912} \qquad (4)$$

Note that the probabilities in the Table confirm previous psycholinguistic findings. To the extent that probability of occurrence reflects salience and/or conceptual importance, an order over the three attributes COLOUR, SIZE and ORIENTATION can be deduced (C>>O>>S), which is compatible with the findings of Pechmann (1989), Belke and Meyer (2002) and others. The locative attributes are also ordered (Y>>X), confirming the findings of Arts (2004) that vertical location is preferred. Orderings deducible from the SG data in turn are excellent predictors of the likelihood of 'propagating' an attribute across disjuncts in a plural description, something which is likely even if an attribute is redundant, modulo the centrality or salience of the attribute in the mental gestalt corresponding to the set. Together with the earlier findings on logical form, the data evinces a dual strategy whereby (a) sets are partitioned based on basic-level conceptual category; (b) elements of the partitions are described using the same attributes if they are easily perceived and conceptualised. Thus, of the descriptions in (3) above, it is (3b) that is the norm among authors.

4 Content determination by partitioning

In this section we describe IA$_{part}$, a partitioning-based content determination algorithm. Though presented as a version of the IA, the basic strategy is generalisable beyond it. For our purposes, the assumption of a preference order will be maintained. IA$_{part}$ is distinguished from the original IA and IA$_{bool}$ (cf. §1) in two respects. First, it induces partitions opportunistically based on KB information, and this is is reflected in the way descriptions are represented. Second,, the criteria whereby a property is added to a description include a consideration of the overall salience or preference of an attribute, and its contribution to the conceptual cohesiveness of the description. Throughout the following discussion, we maintain a running example from Table 1, in which $R = \{e_1, e_2, e_5\}$.

4.1 Partitioned descriptions

IA$_{part}$ generates a *partitioned description* (D_{part}) of a set R, corresponding to a formula in Disjunctive Normal Form. D_{part} is a set of *Description Fragments* (DFs). A DF is a triple $\langle R_{\text{DF}}, T_{\text{DF}}, M_{\text{DF}}\rangle$, where $R_{\text{DF}} \subseteq R$, T_{DF} is a value of TYPE, and M_{DF} is a possibly empty set of other properties. DFs refer to disjoint subsets of R. As the representation suggests, TYPE is given a special status. IA$_{part}$ starts by selecting the basic-level values of TYPE, partitioning R and creating a DF for each element of the partition on this basis. In our example, the selection of TYPE results in two DFs, with M_{DF} initialised to empty:

(5) DF$_1$ $\langle \{e_1, e_5\}, \langle \text{TYPE} : \textit{desk}\rangle, \emptyset\rangle$
DF$_2$ $\langle \{e_2\}, \langle \text{TYPE} : \textit{sofa}\rangle, \emptyset\rangle$

Although neither DF is distinguishing, R_{DF} indicates which referents a fragment is *intended* to identify. In this way, the algorithm incorporates a 'divide-and-conquer' strategy, splitting up the referential intention into 'sub-intentions' to refer to elements of a partition. Following the initial step of selecting TYPE, the algorithm considers other properties in $\mathcal{PO}$. Suppose $\langle$COLOUR : *blue*$\rangle$ is considered first. This property is true of e_2 and e_5. Since DF$_2$ refers to e_2, the new property can be added to M_{DF_2}. Since e_5 is not the sole referent of DF$_1$, the property induces a further partitioning of this fragment, resulting in a new DF. This is identical to DF$_1$ except that it refers only to e_5 and contains $\langle$COLOUR : *blue*$\rangle$. DF$_1$ itself now refers only to e_1. Once $\langle$COLOUR : *red*$\rangle$ is considered, it is added to the latter, yielding (6).

(6) DF$_1$ $\langle \{e_1\}, \langle \text{TYPE} : \textit{desk}\rangle, \{\langle \text{COLOUR} : \textit{red}\rangle\}\rangle$
DF$_2$ $\langle \{e_2\}, \langle \text{TYPE} : \textit{sofa}\rangle, \{\langle \text{COLOUR} : \textit{blue}\rangle\}\rangle$
DF$_3$ $\langle \{e_5\}, \langle \text{TYPE} : \textit{desk}\rangle, \{\langle \text{COLOUR} : \textit{blue}\rangle\}\rangle$

The procedure $updateDescription$, which creates and updates DFs, is formalised in Algorithm 2. When some property $\langle$A : $v\rangle$ is found to be 'useful' in relation to R (in a sense to be made precise), this function is called with two arguments: $\langle$A : $v\rangle$ itself, and $R' = [\![\langle \text{A} : v\rangle]\!] \cap R$, the referents of which $\langle$A : $v\rangle$ is true. The procedure iterates through

[3] A similar analysis using linear regression gave essentially the same results.

Algorithm 2 $updateDescription(\langle \text{A} : v\rangle, R')$

```
1:  for $\langle R_{\text{DF}}, T_{\text{DF}}, M_{\text{DF}}\rangle \in D_{part}$ do
2:      if $R' = \emptyset$ then
3:          return
4:      else if $R_{\text{DF}} \subseteq R'$ then
5:          $M_{\text{DF}} \leftarrow M_{\text{DF}} \cup \{\langle \text{A} : v\rangle\}$
6:          $R' \leftarrow R' - R_{\text{DF}}$
7:      else if $R_{\text{DF}} \cap R' \neq \emptyset$ then
8:          $R_{new} \leftarrow R_{\text{DF}} \cap R'$
9:          $DF_{new} \leftarrow \langle R_{new}, T_{\text{DF}}, M_{\text{DF}} \cup \{\langle \text{A} : v\rangle\} \rangle$
10:         $D_{part} \leftarrow D_{part} \cup \{DF_{new}\}$
11:         $R_{\text{DF}} \leftarrow R_{\text{DF}} - R_{new}$
12:         $R' \leftarrow R' - R_{new}$
13:     end if
14: end for
15: if $\text{A} = \text{TYPE}$ then
16:     $D_{part} \leftarrow D_{part} \cup \{\langle R', \langle \text{A} : v\rangle, \emptyset\rangle\}$
17: else
18:     $D_{part} \leftarrow D_{part} \cup \{\langle R', \bot, \{\langle \text{A} : v\rangle\}\rangle\}$
19: end if
```

the DFs in D_{part}, adding the property to any DF such that $R_{\text{DF}} \cap R' \neq \emptyset$, until R' is empty and all referents in it have been accounted for [2.2]. As indicated in the informal discussion, there are two cases to consider for each DF:

1. $R_{\text{DF}} \subseteq R'$ [2.4]. This corresponds to our example involving $\langle$COLOUR : *blue*$\rangle$ and DF$_2$. The property is simply added to M_{DF} [2.5] and R' is updated by removing the elements thus accounted for [2.6].

2. Suppose $R_{\text{DF}} \not\subseteq R'$. If $R_{\text{DF}} \cap R'$ is empty, then $\langle \text{A} : v\rangle$ is not useful. Suppose on the other hand that $R_{\text{DF}} \cap R' \neq \emptyset$ [2.7]. This occurred with $\langle$COLOUR : *red*$\rangle$ in relation to DF$_1$. The procedure initialises R_{new}, a set holding those referents in R_{DF} which are also in R' [2.8]. A new DF (DF_{new}) is created, which is a copy of the old DF, except that (a) it contains the new property; and (b) its intended referents are R_{new} [2.9]. The new DF is included in the description [2.10], while the old DF is altered by removing R_{new} from R_{DF} [2.11]. This ensures that DFs denote disjoint subsets of R.

Two special cases arise when D_{part} is empty, or there are some elements of R' for which no DF exists. Both cases result in the construction of a new DF. An example of the former case is the initial state of the algorithm, when TYPE is added. As in example (5), the TYPE results in a new DF [2.16]. If a property is not a TYPE, the new DF has T set to null ($\bot$) and the property is included in M [2.18][4]. Note that this procedure easily generalises to the singular case, where D_{part} would only contain one DF.

4.2 Property selection criteria

IA$_{part}$'s content determination strategy maximises the similarity of a set by generating semantically parallel structures. Though contrastiveness plays a role in property selection, the 'preference' or conceptual salience of an attribute is also considered in the decision to propagate it across DFs.

Candidate properties for addition need only be true of at least one element of R. Because of the partitioning strategy, properties are not equally constrastive for all referents. For instance, in (5), e_2 needs to be distinguished from the other sofas in Table 1, while $\{e_1, e_5\}$ need to be distinguished from the desks. Therefore, distractors are held in an associative array C, such that for all $r \in R$, $C[r]$ is the set of distractors for that referent at a given stage in the procedure. Contrastiveness is defined via the following Boolean function:

$$contrastive(\langle \text{A} : v\rangle, R) \leftrightarrow \exists r \in R : \; C[r] - [\![\, \langle \text{A} : v\rangle \,]\!] \neq \emptyset \quad (7)$$

We turn next to salience and similarity. Let $A(D_{part})$ be the set of attributes included in D_{part}. A property is *salient* with respect to D_{part} if it satisfies the following:

$$salient(\langle \text{A} : v\rangle, D_{part}) \leftrightarrow \text{A} \in A(D_{part}) \wedge (.713 \, p(\text{A}, \text{SG})^{.912} > 0.5) \quad (8)$$

that is, the attribute is already included in the description, and the predicted probability of its being propagated in more than one fragment of a description is greater than chance. A potential problem arises here. Consider the description in (5) once more. At this stage, IA$_{part}$ begins to consider COLOUR. The value *red* is true of e_1, but non-contrastive (all the desks which are not in R are red). If this is the first value of COLOUR considered, (8) returns `false` because the attribute has not been used in any part of the description. On later considering $\langle$COLOUR : *blue*$\rangle$, the algorithm adds it to

[4] This only occurs if the KB is *incomplete*, that is, there some entities have no TYPE, so that R is not fully covered by the intended referents of the DFs when TYPE is initially added.

D_{part}, since it is contrastive for $\{e_2, e_5\}$, but will have failed to propagate COLOUR across fragments. As a result, IA$_{part}$ considers values of an attribute in order of *discriminatory power* (Dale, 1989), defined in the present context as follows:

$$\frac{|[\![\langle \textsc{a} : v \rangle]\!] \cap R| \; + |[\![\langle \textsc{a} : v \rangle]\!] - (U - R)|}{|[\![\langle \textsc{a} : v \rangle]\!]|} \tag{9}$$

Discriminatory power depends on the number of referents a property includes in its extension, and the number of distractors $(U - R)$ it removes. By prioritising discriminatory values, the algorithm first considers and adds $\langle$COLOUR : *blue*$\rangle$, and subsequently will include *red* because (8) returns `true`.

To continue with the example, at the stage represented by (6), only e_5 has been distinguished. ORIENTATION, the next attribute considered, is not contrastive for any referent. On considering SIZE, *small* is found to be contrastive for e_1 and e_2, and added to DF$_1$ and DF$_2$. However, SIZE is not added to DF$_3$, in spite of being present in two other fragments. This is because the probability function $p(\text{SIZE}, \text{PPS})$ returns a value below 0.5 (see Table 4, reflecting the relatively low conceptual salience of this attribute. The final description is *the blue desk, the small red desk and the small blue sofa.* This example illustrates the limits set on semantic parallelism and similarity: only attributes which are salient enough are redundantly propagated across DFs.

4.3 Complexity

An estimate of the complexity of IA$_{part}$ must account for the way properties are selected (§4.2) and the way descriptions are updated (Algorithm 2).

Property selection involves checking properties for contrastive value and salience, and updating the ordering of values of each attribute based on discriminatory power (9). Clearly, the number of times this is carried out is bounded by the number of properties in the KB, which we denote n_p. Every time a property is selected, the discriminatory power of values changes (since the number of remaining distractors changes). Now, in the worst case, all n_p properties are selected by the algorithm [5]. Each time, the algorithm must compare the remaining properties pairwise for discriminatory power, a quadratic operation with complexity $O(n_p^2)$. With respect to the procedure $updateDescription$, we need to consider the number of iterations in the for loop starting at line [2.1]. This is bounded by $n_r = |R|$ (there can be no more DFs than there are referents). Once again, if at most n_p properties are selected, then the algorithm makes at most n_r iterations n_p times, yielding complexity $O(n_p n_r)$. Overall, then, IA$_{part}$ has a worst-case runtime complexity $O(n_p^3 n_r)$.

		Mean	**Mode**	PRP
IA$_{bool}$	+ LOC	7.716	7	.7
	− LOC	8.335	7	3.5
IA$_{part}$	+ LOC	4.345	4	6.8
	− LOC	1.93	0	44.7

Table 5: Edit distance scores

5 Evaluation

IA$_{part}$ was compared to van Deemter's IA$_{bool}$ (§1) against human output in the evaluation sub-corpus PL$_2$ ($N = 405$). This was considered an adequate comparison, since IA$_{bool}$ shares with the current framework a genetic relationship with the IA. Other approaches, such as Gardent's (2002) brevity-oriented algorithm, would perform poorly on our data. As shown in §3, overspecification is extremely common in plural descriptions, suggesting that such a strategy is on the wrong track (but see §6).

IA$_{part}$ and IA$_{bool}$ were each run over the domain representation paired with each corpus description. The output logical form was compared to the LF compiled from the XML representation of an author's description (cf. Figure 1). LFs were represented as *and-or* trees, and compared using the tree edit distance algorithm of Shasha and Zhang (1990). On this measure, a value of 0 indicates identity.

Because only a subset of descriptions contain locative expressions, PL$_2$ was divided into a +LOC dataset ($N = 148$) and a −LOC dataset ($N = 257$). The preference orders for both algorithms were (C>>O>>S) for −LOC and (Y>>C>>X>>S>>O) for +LOC. These are suggested by the attribute probabilities in Table 4. Table 5 displays the mean Edit score obtained by each algorithm on the two datasets, the modal (most frequent) value, and the *perfect recall percentage* (PRP), the proportion of Edit scores of 0, indicating

[5] Only unique properties need to be considered, as each property is selected at most once, though it can be included in more than one DF.

perfect agreement with an author.

As the means and modes indicate, IA$_{part}$ outperformed IA$_{bool}$ on both datasets, with a consistently higher PRP (this coincides with the modal score in the case of $-$LOC). Pairwise $t-$tests showed that the trends were significant in both $+$LOC ($t(147) = 9.28$, $p < .001$) and $-$LOC ($t(256) = 10.039$, $p < .001$).

IA$_{bool}$ has a higher (worse) mean on $-$LOC, but a better PRP than on $+$LOC. This apparent discrepancy is partly due to variance in the edit distance scores. For instance, because the Y attribute was highest in the preference order for $+$LOC, there were occasions when both referents could be identified using the same value of Y, which was therefore included by IA$_{bool}$ at first pass, before considering disjunctions. Since Y was highly preferred by authors (see Table 4), there was higher agreement on these cases, compared to those where the values of Y were different for the two referents. In the latter case, Y was only when disjunctions were considered, if at all. The worse performance of IA$_{part}$ on $+$LOC is due to a larger choice of attributes, also resulting in greater variance, and occasionally incurring higher Edit cost when the algorithm overspecified more than a human author. This is a potential shortcoming of the partitioning strategy outlined here, when it is applied to more complex domains.

Some example outputs are given below, in a domain where COLOUR sufficed to distinguish the referents, which had different values of this attribute (i.e. an instance of the VDS condition). The formula returned by IA$_{part}$ (10a) is identical to the (LF of) the human-authored description (with Edit score of 0). The output of IA$_{bool}$ is shown in (10b).

(10) (a) $\big(\textit{fan} \wedge \textit{green}\big) \vee \big(\textit{sofa} \wedge \textit{blue}\big)$
‘the green fan and the big sofa’
(b) $\big(\textit{sofa} \vee \textit{fan}\big) \wedge \textit{small} \wedge \textit{front} \wedge \big(\textit{blue} \vee \textit{green}\big)$
‘the small, blue and green sofa and fan’

As a result of IA$_{bool}$’s requiring a property or disjunction to be true of the the entire set of referents, COLOUR is not included until disjunctions are considered, while values of SIZE and ORIENTATION are included at first pass. By contrast, IA$_{part}$ includes COLOUR before any other attribute apart from TYPE. Though overspecification is common in our data, IA$_{bool}$ overspecifies with the ‘wrong’ attributes (those which are relatively dispreferred). The rationale in IA$_{part}$ is to overspecify only if a property will enhance referent similarity, and is sufficiently salient. As for logical form, the Conjunctive Normal Form output of IA$_{bool}$ increases the Edit score, given the larger number of logical operators in (10b) compared to (10a).

6 Summary and conclusions

This paper presented a study of plural reference, showing that people (a) partition sets based on the basic level TYPE or category of their elements and (b) redundantly propagate attributes across disjuncts in a description, modulo their salience. Our algorithm partitions a set opportunistically, and incorporates a corpus-derived heuristic to estimate the salience of a property. Evaluation results showed that these principles are on the right track, with significantly better performance over a previous model (van Deemter, 2002). The partitioning strategy is related to a proposal by van Deemter and Krahmer (2007), which performs exhaustive search for a partition of a set whose elements can be described non-disjunctively. Unlike the present approach, this algorithm is non-incremental and computationally costly.

IA$_{part}$ initially performs partitioning based on the basic-level TYPE of objects, in line with the evidence. However, later partitions can be induced by other properties, possible yielding partitions even with same-TYPE referents (e.g. *the blue chair and the red chair*). Aggregation (*the blue and red chairs*) may be desirable in such cases, but limits on syntactic complexity of NPs are bound to play a role (Horacek, 2004). Another possible limitation of IA$_{part}$ is that, despite strong evidence for overspecification, complex domains could yield very lengthy outputs. Strategies to avoid them include the utilisation of other boolean operators like negation (*the desks which are not red*) (Horacek, 2004). These issues are open to future empirical research.

A Comparative Evaluation of Deep and Shallow Approaches to the Automatic Detection of Common Grammatical Errors

Abstract

This paper compares a deep and a shallow processing approach to the problem of classifying a sentence as grammatically well-formed or ill-formed. The deep processing approach uses the XLE LFG parser and English grammar: two versions are presented, one which uses the XLE directly to perform the classification, and another one which uses a decision tree trained on features consisting of the XLE's output statistics. The shallow processing approach predicts grammaticality based on n-gram frequency statistics: we present two versions, one which uses frequency thresholds and one which uses a decision tree trained on the frequencies of the rarest n-grams in the input sentence. We find that the use of a decision tree improves on the basic approach only for the deep parser-based approach. We also show that combining both the shallow and deep decision tree features is effective. Our evaluation is carried out using a large test set of grammatical and ungrammatical sentences. The ungrammatical test set is generated automatically by inserting grammatical errors into well-formed BNC sentences.

1 Introduction

This paper is concerned with the task of predicting whether a sentence contains a grammatical error. An accurate method for carrying out automatic grammaticality judgements has uses in the areas of computer-assisted language learning and grammar checking. Comparative evaluation of existing error detection approaches has been hampered by a lack of large and commonly used evaluation error corpora. We attempt to overcome this by automatically creating a large error corpus, containing four different types of frequently occurring grammatical errors. We use this corpus to evaluate the performance of two approaches to the task of automatic error detection. One approach uses low-level detection techniques based on POS n-grams. The other approach is a novel parser-based method which employs deep linguistic processing to discriminate grammatical input from ungrammatical. For both approaches, we implement a basic solution, and then attempt to improve upon this solution using a decision tree classifier. We show that combining both methods improves upon the individual methods.

N-gram-based approaches to the problem of error detection have been proposed and implemented in various forms by Atwell(1987), Bigert and Knutsson (2002), and Chodorow and Leacock (2000) amongst others. Existing approaches are hard to compare since they are evaluated on different test sets which vary in size and error density. Furthermore, most of these approaches concentrate on one type of grammatical error only, namely, context-sensitive or real-word spelling errors. We implement a vanilla n-gram-based approach which is tested on a very large test set containing four different types of error.

The idea behind the parser-based approach to error detection is to use a broad-coverage hand-crafted precision grammar to detect ungrammatical sen-

tences. This approach exploits the fact that a precision grammar is designed, in the traditional generative grammar sense (Chomsky, 1957), to distinguish grammatical sentences from ungrammatical sentences. This is in contrast to treebank-based grammars which tend to massively overgenerate and do not generally aim to discriminate between the two. In order for our approach to work, the coverage of the precision grammars must be broad enough to parse a large corpus of grammatical sentences, and for this reason, we choose the XLE (Maxwell and Kaplan, 1996), an efficient and robust parsing system for Lexical Functional Grammar (LFG) (Kaplan and Bresnan, 1982) and the ParGram English grammar (Butt et al., 2002) for our experiments. This system employs robustness techniques, some borrowed from Optimality Theory (OT) (Prince and Smolensky, 1993), to parse extra-grammatical input (Frank et al., 1998), but crucially still distinguishes between optimal and suboptimal solutions.

The evaluation corpus is a subset of an ungrammatical version of the British National Corpus (BNC), a 100 million word balanced corpus of British English (Burnard, 2000). This corpus is obtained by automatically inserting grammatical errors into the original BNC sentences based on an analysis of a manually compiled "real" error corpus.

This paper makes the following contributions to the task of automatic error detection:

1. A novel deep processing XLE-based approach
2. An effective and novel application of decision tree machine learning to both shallow and deep approaches
3. A novel combination of deep and shallow processing
4. An evaluation of an n-gram-based approach on a wider variety of errors than has previously been carried out
5. A large evaluation error corpus

The paper is organised as follows: in Section 2, we describe previous approaches to the problem of error detection; in Section 3, a description of the error corpus used in our evaluation experiments is presented, and in Section 4, the two approaches to error detection are presented, evaluated, combined and compared. Section 5 provides a summary and suggestions for future work.

2 Background

2.1 Precision Grammars

A precision grammar is a formal grammar designed to distinguish ungrammatical from grammatical sentences. This is in contrast to large treebank-induced grammars which often accept ungrammatical input (Charniak, 1996). While high coverage is required, it is difficult to increase coverage without also increasing the amount of ungrammatical sentences that are accepted as grammatical by the grammar. Most publications in grammar-based automatic error detection focus on locating and categorising errors and giving feedback. Existing grammars are re-used (Vandeventer Faltin, 2003), or grammars of limited size are developed from scratch (Reuer, 2003).

The ParGram English LFG is a hand-crafted broad-coverage grammar developed over several years with the XLE platform (Butt et al., 2002). The XLE parser uses OT to resolve ambiguities (Prince and Smolensky, 1993). Grammar constraints resulting in rare constructions can be marked as "dispreferred" and constraints resulting in common ungrammatical constructions can be marked as "ungrammatical". The use of constraint ordering and marking increases the robustness of the grammar, while maintaining the grammatical / ungrammatical distinction (Frank et al., 1998). The English Resource Grammar (ERG) is a precision Head-Driven Phrase Structure Grammar (HPSG) of English (Copestake and Flickinger, 2000; Pollard and Sag, 1994). Its coverage is not as broad as the XLE English grammar. Baldwin et al. (2004) propose a method to identify gaps in the grammar. Blunsom and Baldwin (2006) report ongoing development.

There has been previous work using the ERG and the XLE grammars in the area of computer-assisted language learning. Bender et al. (2004) use a version of the ERG containing mal-rules to parse ill-formed sentences from the SST corpus of Japanese learner English (Emi et al., 2004). They then use the semantic representations of the ill-formed input to generate well-formed corrections. Khader et al. (2004) study whether the ParGram English LFG can be used for computer-assisted language learning by adding additional OT marks for ungrammatical constructions observed in a learner corpus. However, the evaluation is preliminary, on only 50 test items.

2.2 N-gram Methods

Most shallow approaches to grammar error detection originate from the area of real-word spelling error correction. A real-word spelling error is a spelling or typing error which results in a token which is another valid word of the language in question.

The (to our knowledge) oldest work in this area is that of Atwell (1987) who uses a POS tagger to flag POS bigrams that are unlikely according to a reference corpus. While he speculates that the bigram frequency should be compared to how often the same POS bigram is involved in errors in an error corpus, the proposed system uses the raw frequency with an empirically established threshold to decide whether a bigram indicates an error. In the same paper, a completely different approach is presented that uses the same POS tagger to consider spelling variants that have a different POS. In the example sentence *I am very **hit*** the POS of the spelling variant *hot/JJ* is added to the list NN-VB-VBD-VBN of possible POS tags of *hit*. If the POS tagger chooses *hit/JJ*, the word is flagged and the correction *hot* is proposed to the user. Unlike most n-gram-based approaches, Atwell's work aims to detect grammar errors in general and not just real-word spelling errors. However, a complete evaluation is missing.

The idea of disambiguating between the elements of confusion sets is related to word sense disambiguation. Golding (1995) builds a classifier based on a rich set of context features. Mays et al. (1991) apply the noisy channel model to the disambiguation problem. For each candidate correction S' of the input S the probability $P(S')P(S|S')$ is calculated and the most likely correction selected. This method is re-evaluated by Wilcox-O'Hearn et al. (2006) on WSJ data with artificial real-word spelling errors.

Bigert and Knutsson (2002) extend upon a basic n-gram approach by attempting to match n-grams of low frequency with similar n-grams in order to reduce overflagging. Furthermore, n-grams crossing clause boundaries are not flagged and the similarity measure is adapted in the case of phrase boundaries that usually result in low frequency n-grams.

Chodorow and Leacock (2000) use a mutual information measure in addition to raw frequency of n-grams. Apart from this, their ALEK system employs other extensions to the basic approach, for example frequency counts from both generic and word-specific corpora are used in the measures. It is not reported how much each of these contribute to the overall performance.

Rather than trying to implement all of the previous n-gram approaches, we implement the basic approach which uses rare n-grams to predict grammaticality. This property is shared by all previous shallow approaches. We also test our approach on a wider class of grammatical errors.

3 Ungrammatical Data

In this section, we discuss the notion of an artificial error corpus (Section 3.1), define the type of ungrammatical language we are dealing with (Section 3.2), and describe our procedure for creating a large artificial error corpus derived from the BNC (Section 3.3).

3.1 An Artificial Error Corpus

In order to meaningfully evaluate a shallow versus deep approach to automatic error detection, a large test set of ungrammatical sentences is needed. A corpus of ungrammatical sentences can take the form of a learner corpus (Granger, 1993; Emi et al., 2004), i. e. a corpus of sentences produced by language learners, or it can take the form of a more general error corpus comprising sentences which are not necessarily produced in a language-learning context and which contain competence and performance errors produced by native and non-native speakers of the language (Becker et al., 1999; Foster and Vogel, 2004; Foster, 2005). For both types of error corpus, it is not enough to collect a large set of sentences which are likely to contain an error - it is also necessary to examine each sentence in order to determine whether an error has actually occurred, and, if it has, to note the nature of the error. Thus, like the creation of a treebank, the creation of a corpus of ungrammatical sentences requires time and linguistic knowledge, and is by no means a trivial task.

A corpus of ungrammatical sentences which is large enough to be useful can be created automatically by inserting, deleting or replacing words in grammatical sentences. These transformations should be linguistically realistic and should, therefore, be based on an analysis of naturally produced grammatical errors. Automatically generated error corpora have been used before in natural language processing. Bigert (2004) and Wilcox-O'Hearn et al. (2006), for example, automatically introduce spelling errors into texts. Here, we generate a large error corpus by automatically inserting four different kinds of grammatical errors into BNC sentences.

3.2 Commonly Produced Grammatical Errors

Following Foster (2005), we define a sentence to be ungrammatical if all the words in the sentence are well-formed words of the language in question, but the sentence contains one or more error. This error can take the form of a performance slip which can occur due to carelessness or tiredness, or a competence error which occurs due to a lack of knowledge of a particular construction. This definition includes real-word spelling errors and excludes non-word spelling errors. It also excludes the abbreviated informal language used in electronic communication. Using the above definition as a guideline, a 20,000 word corpus of ungrammatical English sentences was collected from a variety of written texts including newspapers, academic papers, emails and website forums (Foster and Vogel, 2004; Foster, 2005). The errors in the corpus were carefully analysed and classified in terms of how they might be corrected using the three word-level correction operators: insert, delete and substitute. The following frequency ordering of the three word-level correction operators was found:
substitute (48%) > *insert* (24%) > *delete* (17%) > *combination* (11%)
Stemberger (1982) reports the same ordering of the substitution, deletion and insertion correction operators in a study of native speaker spoken language slips. Among the grammatical errors which can be corrected by substituting one word for another, the most common errors are real-word spelling errors and agreement errors. In fact, 72% of all errors fall into one of the following four classes:

1. missing word errors:
   *What **are** the subjects? > What the subjects?*
2. extra word errors:
   *Was that in the summer? > Was that in the summer **in**?*
3. real-word spelling errors:
   *She could **not** comprehend. > She could **no** comprehend.*
4. agreement errors:
   *She steered Melissa round a corner. > She steered Melissa round a **corners**.*

A similar classification was adopted by Nicholls (1999), having analysed the errors in a learner corpus. Our research is currently limited to the four error types given above, i. e. missing word errors, extra word errors, real-word spelling errors and agreements errors. However, it is possible for it to be extended to handle a wider class of errors.

3.3 Automatic Error Creation

The error creation procedure takes as input a part-of-speech-tagged corpus of sentences which are assumed to be well-formed, and outputs a corpus of ungrammatical sentences. The automatically introduced errors take the form of the four most common error types found in the manually created corpus, i. e. missing word errors, extra word errors, real-word spelling errors and agreement errors. For each sentence in the original tagged corpus, an attempt is made to automatically produce four ungrammatical sentences, one for each of the four error types. Thus, the output of the error creation procedure is, in fact, four error corpora.

3.3.1 Missing Word Errors

In the manually created error corpus of Foster (2005), missing word errors are classified based on the part-of-speech (POS) of the missing word. 98% of the missing parts-of-speech come from the following list (the frequency distribution in the error corpus is given in brackets):
det (28%) > verb (23%) > prep (21%) > pro (10%) > noun (7%) > "to" (7%) > conj (2%)
We use this information when introducing missing word errors into the BNC sentences. For each sentence, all words with the above POS tags are noted. One of these is selected and deleted. The above frequency ordering is respected so that, for example, missing determiner errors are produced more often than missing pronoun errors. No ungrammatical

sentence is produced if the original sentence contains just one word or if the sentence contains no words with parts-of-speech in the above list.

3.3.2 Extra Word Errors

We introduce extra word errors in the following three ways:

1. Random duplication of any token within a sentence: *That's the way* ***we we*** *learn here.*
2. Random duplication of any POS within a sentence: *There* ***it he*** *was.*
3. Random insertion of an arbitrary token into the sentence: *Joanna drew* ***as*** *a long breadth.*

Apart from the case of duplicate tokens, the extra words are selected from a list of tagged words compiled from a random subset of the BNC. Again, our procedure for inserting extra words is based on the analysis of extra word errors in the 20,000 word error corpus of Foster (2005).

3.3.3 Real-Word Spelling Errors

We classify an error as a real-word spelling error if it can be corrected by replacing the erroneous word with another word with a Levenshtein distance of one from the erroneous word, e.g. *the* and *they*. Based on the analysis of the manually created error corpus (Foster, 2005), we compile a list of common English real-word spelling error word pairs. For each BNC sentence, the error creation procedure records all tokens in the sentence which appear as one half of one of these word pairs. One token is selected at random and replaced by the other half of the pair. The list of common real-word spelling error pairs contains such frequently occurring words as *is* and *a*, and the procedure therefore produces an ill-formed sentence for most input sentences.

3.3.4 Agreement Errors

We introduce subject-verb and determiner-noun number agreement errors into the BNC sentences. We consider both types of agreement error equally likely and introduce the error by replacing a singular determiner, noun or verb with its plural counterpart, or vice versa. For English, subject-verb agreement errors can only be introduced for present tense verbs, and determiner-noun agreement errors can only be introduced for determiners which are marked for number, e.g. demonstratives and the indefinite article. The procedure would be more productive if applied to a morphologically richer language.

3.3.5 Covert Errors

James (1998) uses the term *covert error* to describe a genuine language error which results in a sentence which is syntactically well-formed under some interpretation different from the intended one. The prominence of covert errors in our automatically created error corpus is estimated by manually inspecting 100 sentences of each error type. The percentage of grammatical structures that are inadvertently produced for each error type and an example of each one are shown below:

- Agreement Errors, 7%
  Mary's staff ***include*** *Jones,Smith and Murphy* $>$ *Mary's staff* ***includes*** *Jones,Smith and Murphy*
- Real-Word Spelling Errors, 10%
  And ***then****?* $>$ *And* ***them****?*
- Extra Word Errors, 5%
  in defiance of the free rider prediction $>$ *in defiance of the free rider* ***near*** *prediction*
- Missing Word Errors, 13%
  She steered ***Melissa*** *round a corner* $>$ *She steered round a corner*

The occurrence of these *covert errors* can be reduced by fine-tuning the error creation procedure but they can never be completely eliminated. Indeed, they should not be eliminated from the test data, because, ideally, an optimal error detection system should be sophisticated enough to flag syntactically well-formed sentences containing covert errors as potentially ill-formed.[1]

4 Error Detection Evaluation

In this section we present the error detection evaluation experiments. The experimental setup is explained in Section 4.1, the results are presented in Section 4.2 and they are analysed in Section 4.3.

[1] An example of this is given in the XLE User Documentation (`http://www2.parc.com/isl/groups/nltt/xle/doc/`). The authors remark that an ungrammatical reading of the sentence *Lets go to the store* in which *Lets* is missing an apostrophe, is preferable to the grammatical yet implausible analysis in which *Lets* is a plural noun.

4.1 Experimental Setup

4.1.1 Test Data and Evaluation Procedure

The following steps are carried out to produce training and test data for this experiment:

1. Speech material, poems, captions and list items are removed from the BNC. 4.2 million sentences remain. The order of sentences is randomised.
2. For the purpose of cross-validation, the corpus is split into 10 parts.
3. Each part is passed to the 4 automatic error insertion modules described in Section 3.3, resulting in 40 additional sets of varying size.
4. The first 60,000 sentences of each of the 50 sets, i. e. 3 million sentences, are parsed with XLE.[2]
5. N-gram frequency information is extracted for the first 60,000 sentences of each set. An additional 20,000 is extracted as held-out data.
6. 10 sets with mixed error types are produced by joining a quarter of each respective error set.
7. For each error type (including mixed errors) and cross-validation set, the 60,000 grammatical and 60,000 ungrammatical sentences are joined.
8. Each cross-validation run uses one set out of the 10 as test data (120,000 sentences) and the remaining 9 sets for training (1,080,000 sentences).

The experiment is a standard binary classification task. The methods classify the sentences of the test sets as grammatical or ungrammatical. We use the standard measures of precision, recall, f-score and accuracy (Figure 1). True positives are understood to be ungrammatical sentences that are identified as such. The baseline precision and accuracy is 50% as half of the test data is ungrammatical. If 100% of the test data is classified as ungrammatical, recall will be 100% and f-score $2/3$. Recall shows the accuracy we would get if the grammatical half of the test data was removed. Parametrised methods are first optimised for accuracy and then the other measures are taken. Therefore, f-scores below the artificial $2/3$ baseline are meaningful.

Measure	**Formula**
precision	$tp/(tp + fp)$
recall	$tp/(tp + fn)$
f-score	$2pr * re/(pr + re)$
accuracy	$(tp + tn)/(tp + tn + fp + fn)$

Figure 1: Evaluation measures: tp = true positives, fp = false positives, tn = true negatives, fn = false negatives, pr = precision, re = recall

4.1.2 Method 1: Precision Grammar

According to the XLE documentation, a sentence is marked with a star (*) if its optimal solution uses a constraint marked as ungrammatical. We use this star feature, parser exceptions and zero number of parses to classify a sentence as ungrammatical.

4.1.3 Method 2: POS N-grams

In each cross-validation run, the full data of the remaining 9 sets of step 2 of the data generation (see Section 4.1.1) is used as a reference corpus of $0.9 \times 4,200,000 = 3,800,000$ assumedly grammatical sentences. The reference corpora and data sets are POS tagged with the IMS TreeTagger (Schmidt, 1994). Frequencies of POS n-grams ($n = 2, \ldots, 7$) are counted in the reference corpora. A test sentence is flagged as ungrammatical if it contains an n-gram below a fixed frequency threshold. Method 2 has two parameters: n and the frequency threshold.

4.1.4 Method 3: Decision Trees on XLE Output

The XLE parser outputs additional statistics for each sentence that we encode in six features:

- An integer indicating starredness (0 or 1) and various parser exceptions (-1 for time out, -2 for exceeded memory, etc.)
- The number of optimal parses[3]
- The number of unoptimal parses
- The duration of parsing
- The number of subtrees
- The number of words

[2] We use the XLE command *parse-testfile* with *parse-literally* set to 1, *max xle scratch storage* set to 1,000 MB, *timeout* to 60 seconds, and the XLE English LFG. Skimming is not switched on and fragments are.

[3] The use of preferred versus dispreferred constraints are used to distinguish optimal parses from unoptimal ones.

Training data for the decision tree learner is composed of $9 \times 60,000 = 540,000$ feature vectors from grammatical sentences and $9 \times 15,000 = 135,000$ feature vectors from ungrammatical sentences of each error type, resulting in equal amounts of grammatical and ungrammatical training data.

We choose the weka implementation of machine learning algorithms for the experiments (Witten and Frank, 2000). We use a J48 decision tree learner with the default model.

4.1.5 Method 4: Decision Trees on N-grams

Method 4 follows the setup of Method 3. However, the features are the frequencies of the rarest n-grams ($n = 2, \ldots, 7$) in the sentence. Therefore, the feature vector of one sentence contains 6 numbers.

4.1.6 Method 5: Decision Trees on Combined Feature Sets

This method combines the features of Methods 3 and 4 for training a decision tree.

4.2 Results

Table 1 shows the results for Method 1, which uses XLE starredness, parser exceptions[4] and zero parses to classify grammaticality. Table 2 shows the results for Method 2, the basic n-gram approach. Table 3 shows the results for Method 3, which classifies based on a decision tree of XLE features. The results for Method 4, the n-gram-based decision tree approach, are shown in Table 4. Finally, Table 5 shows the results for Method 5 which combines n-gram and XLE features in decision trees.

In the case of Method 2, we first have to find optimal parameters. As only very limited integer values for n and the threshold are reasonable, an exhaustive search is feasible. We considered $n = 2, \ldots, 7$ and frequency thresholds below 20,000. Separate held-out data (400,000 sentences) is used in order to avoid overfitting. Best accuracy is achieved with 5-grams and a threshold of 4. Table 2 reports results with these parameters.

Error type	**Pr.**	**Re.**	**F-Sc.**	**Acc.**
Agreement	66.2	64.6	65.4	65.8
Real-word	63.5	57.3	60.3	62.2
Extra word	64.4	59.7	62.0	63.4
Missing word	59.2	47.8	52.9	57.4
Mixed errors	63.5	57.3	60.3	62.2

Table 1: Classification results with XLE starredness, parser exceptions and zero parses (Method 1)

Error type	**Pr.**	**Re.**	**F-Sc.**	**Acc.**
Agreement	58.6	51.7	55.0	57.6
Real-word	64.0	64.9	64.5	64.2
Extra word	64.8	67.3	66.0	65.4
Missing word	57.2	48.8	52.7	56.1
Mixed errors	61.5	58.2	59.8	60.8

Table 2: Classification results with 5-gram and frequency threshold 4 (Method 2)

The standard deviation of results across cross-validation runs is below 0.006 on all measures, except for Method 4. Therefore we only report average percentages. The highest observed standard deviation is 0.0257 for recall of Method 4 on agreement errors.

For Methods 3, 4 and 5, the decision tree learner optimises accuracy and, in doing so, chooses a trade-off between precision and recall.

4.3 Analysis

Both Method 1 (Table 1) and Method 2 (Table 2) achieve above baseline accuracy for all error types. However, Method 1, which uses the XLE starred feature, parser exceptions and zero parses to determine whether or not a sentence is grammatical, slightly outperforms Method 2, which uses the fre-

Error type	**Pr.**	**Re.**	**F-Sc.**	**Acc.**
Agreement	67.0	79.3	72.6	70.1
Real-word	63.4	67.6	65.4	64.3
Extra word	63.0	66.4	64.7	63.7
Missing word	59.7	57.8	58.7	59.4
Mixed errors	63.4	67.8	65.6	64.4

Table 3: Classification results with decision tree on XLE output (Method 3)

[4] XLE parsing (see footnote 2 for configuration) runs out of time for 0.7 % and out of memory for 2.5 % of sentences, measured on training data of the first cross-validation run, i. e. 540,000 grammatical sentence and 135,000 of each error type. 14 sentences of 3 million caused the parser to terminate abnormally.

Error type	Pr.	Re.	F-Sc.	Acc.
Agreement	61.2	53.8	57.3	59.9
Real-word	65.3	64.3	64.8	65.1
Extra word	66.4	67.4	66.9	66.7
Missing word	59.1	49.2	53.7	57.5
Mixed errors	63.3	58.7	60.9	62.3

Table 4: Classification results with decision tree on vectors of frequency of rarest n-grams (Method 4)

Error type	Pr.	Re.	F-Sc.	Acc.
Agreement	67.1	75.2	70.9	69.2
Real-word	65.8	70.7	68.1	67.0
Extra word	65.9	71.2	68.5	67.2
Missing word	61.2	58.0	59.5	60.6
Mixed errors	65.2	68.8	66.9	66.0

Table 5: Classification results with decision tree on joined feature set (Method 5)

quency of POS 5-grams to detect an error. The XLE deep-processing approach is better than the n-gram-based approach for agreement errors (f-score +10.4). Examining the various types of agreement errors, we can see that this is especially the case for singular subjects followed by plural copula verbs (recall +37.7) and determiner-noun number mismatches (recall +23.6 for singular nouns and +18.0 for plural nouns), but not for plural subjects followed by singular verbs (recall -24.0). The relatively poor performance of Method 2 on agreement errors involving determiners could be due to the lack of agreement marking on the Penn Treebank determiner tag used by TreeTagger.

Method 1 is outperformed by Method 2 for real-word spelling and extra word errors (f-score -4.2, -4.0). Unsurprisingly, Method 2 has an advantage on those real-word spelling errors that change the POS (recall -8.8 for Method 1). Both methods perform poorly on missing word errors. For both methods there are only very small differences in performance between the various missing word error subtypes (identified by the POS of the deleted word).

Method 3, which uses machine learning to exploit all the information returned by the XLE parser, improves performance from Method 1, the basic XLE method, for all error types.[5] The general improvement comes from an improvement in recall, meaning that more ungrammatical sentences are actually flagged as such without compromising precision. The improvement is highest for agreement errors (f-score +7.2). Singular subject with plural copula errors (e. g. *The man are*) peak at a recall of 91.0. The Method 3 results indicate that information on the number of solutions (optimal and unoptimal), the number of subtrees, the time taken to parse the sentence and the number of words can be used to predict grammaticality. It would be interesting to investigate this approach with other parsers.

Method 4, which uses a decision tree with n-gram-based features, confirms the results of Method 2. The decision trees' root nodes are similar or even identical (depending on cross-validation run) to the decision rule of Method 2 (5-gram frequency below 4). However, the 10 decision trees have between 1,111 and 1,905 nodes and draw from all features, even bigrams and 7-grams that perform poorly on their own. The improvements are very small though and they are not significant according the criterion of non-overlapping cross-validation results. The main reason for the evaluation of Method 4 is to provide another reference point for comparison of the final method.

The overall best results are those for Method 5, the combined XLE, n-gram and machine-learning-based method, which outperforms the next best method, Method 3, on all error types apart from agreement errors (f-score -1.7, +2.7, +3.8, +0.8). For agreement errors, it seems that the relatively poor results for n-grams have a negative effect on the relatively good results for the XLE. Figure 2 shows that the performance is almost constant on ungrammatical data in the important sentence length range from 5 to 40. However, there is a negative correlation of accuracy and sentence length for grammatical sentences. Very long sentences of any kind tend to be classified as ungrammatical, except for missing word errors which remain close to the 50% baseline of coin-flipping.

For all methods, missing word errors are the worst-performing, particularly in recall (i. e. the ac-

[5] The +0.3 increase in average accuracy for extra word errors is not clearly significant as the results of cross-validation runs overlap.

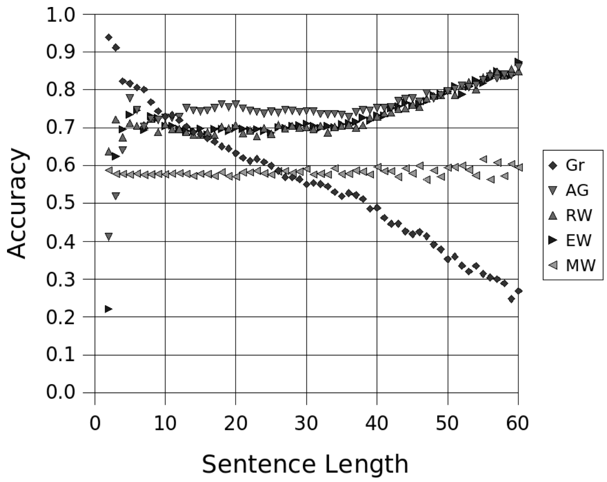

Figure 2: Accuracy by sentence length for Method 5 measured on separate grammatical and ungrammatical data: Gr = Grammatical, AG = Agreement, RW = Real-Word, EW = Extra Word, MW = Missing Word

curacy on ungrammatical data alone). This means that the omission of a word is less likely to result in the sentence being flagged as erroneous. In contrast, extra word errors perform consistently and relatively well for all methods.

5 Conclusion and Future Work

We evaluated a deep processing approach and a POS n-gram-based approach to the automatic detection of common grammatical errors in a BNC-derived artificial error corpus. The results are broken down by error type. Together with the deep approach, a decision tree machine learning algorithm can be used effectively. However, extending the shallow approach with the same learning algorithm gives only small improvements. Combining the deep and shallow approaches gives an additional improvement on all but one error type.

Our plan is to investigate why all methods perform poorly on missing word errors, to extend the error creation procedure so that it includes a wider range of errors, to try the deep approach with other parsers, to integrate additional features from state-of-the-art shallow techniques and to repeat the experiments for languages other than English.

Acknowledgements

This work is supported by the IRCSET Embark Initiative (basic research grant SC/02/298 and postdoctoral fellowship P/04/232). The training and test data used in this reseach is based on the British National Corpus (BNC), distributed by Oxford University Computing Services on behalf of the BNC Consortium. We thank Djamé Seddah for helping us to run the XLE parsing on the SFI/HEA Irish Centre for High-End Computing (ICHEC) and the authors wish to acknowledge ICHEC for the provision of computational facilities and support.

Abstract

We present a comparative error analysis of the two dominant approaches in data-driven dependency parsing: global, exhaustive, graph-based models, and local, greedy, transition-based models. We show that, in spite of similar performance overall, the two models produce different types of errors, in a way that can be explained by theoretical properties of the two models. This analysis leads to new directions for parser development.

1 Introduction

Syntactic dependency representations have a long history in descriptive and theoretical linguistics and many formal models have been advanced (Hudson, 1984; Mel'čuk, 1988; Sgall et al., 1986; Maruyama, 1990). A dependency graph of a sentence represents each word and its syntactic modifiers through labeled directed arcs, as shown in Figure 1, taken from the Prague Dependency Treebank (Böhmová et al., 2003). A primary advantage of dependency representations is that they have a natural mechanism for representing discontinuous constructions, arising from long distance dependencies or free word order, through *non-projective* dependency arcs, exemplified by the arc from *jedna* to *Z* in Figure 1.

Syntactic dependency graphs have recently gained a wide interest in the computational linguistics community and have been successfully employed for many problems ranging from machine translation (Ding and Palmer, 2004) to ontology construction (Snow et al., 2004). In this work we focus on a common parsing paradigm called *data-driven dependency parsing*. Unlike grammar-based parsing, data-driven approaches learn to produce dependency graphs for sentences solely from an annotated corpus. The advantage of such models is that they are easily ported to any domain or language in which annotated resources exist.

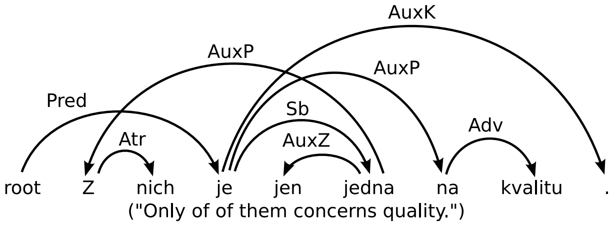

Figure 1: Example dependency graph.

As evident from the CoNLL-X shared task on dependency parsing (Buchholz and Marsi, 2006), there are currently two dominant models for data-driven dependency parsing. The first is what Buchholz and Marsi (2006) call the "all-pairs" approach, where every possible arc is considered in the construction of the optimal parse. The second is the "stepwise" approach, where the optimal parse is built stepwise and where the subset of possible arcs considered depend on previous decisions. Theoretically, these models are extremely different. The all-pairs models are globally trained, use exact (or near exact) inference algorithms, and define features over a limited history of parsing decisions. The stepwise models use local training and greedy inference algorithms, but define features over a rich history of parse decisions. However, both models obtain similar parsing accuracies

on a variety of languages, as seen in Table 1, which shows results for the two top performing systems in the CoNLL-X shared task, McDonald et al. (2006) ("all-pairs") and Nivre et al. (2006) ("stepwise").

Despite the similar performance in terms of overall accuracy, there are indications that the two types of models exhibit different behaviour. For example, Sagae and Lavie (2006) displayed that combining the predictions of both parsing models can lead to significantly improved accuracies. In order to pave the way for new and better methods, a much more detailed error analysis is needed to understand the strengths and weaknesses of different approaches. In this work we set out to do just that, focusing on the two top performing systems from the CoNLL-X shared task as representatives of the two dominant models in data-driven dependency parsing.

2 Two Models for Dependency Parsing

2.1 Preliminaries

Let $L = \{l_1, \ldots, l_{|L|}\}$ be a set of permissible arc labels. Let $x = w_0, w_1, \ldots, w_n$ be an input sentence where w_0=*root*. Formally, a dependency graph for an input sentence x is a labeled directed graph $G = (V, A)$ consisting of a set of nodes V and a set of labeled directed arcs $A \subseteq V \times V \times L$, i.e., if $(i, j, l) \in A$ for $i, j \in V$ and $l \in L$, then there is an arc from node i to node j with label l in the graph. A dependency graph G for sentence x must satisfy the following properties:

1. $V = \{0, 1, \ldots, n\}$
2. If $(i, j, l) \in A$, then $j \neq 0$.
3. If $(i, j, l) \in A$, then for all $i' \in V - \{i\}$ and $l' \in L$, $(i', j, l') \notin A$.
4. For all $j \in V - \{0\}$, there is a (possibly empty) sequence of nodes $i_1, \ldots, i_m \in V$ and labels $l_1, \ldots, l_m, l \in L$ such that $(0, i_1, l_1)$,(i_1, i_2, l_2), $\ldots, (i_m, j, l) \in A$.

The constraints state that the dependency graph spans the entire input (1); that the node 0 is a root (2); that each node has at most one incoming arc in the graph (3); and that the graph is connected through directed paths from the node 0 to every other node in the graph (4). A dependency graph satisfying these constraints is a directed tree originating out of the root node 0. We say that an arc (i, j, l) is *non-projective* if not all words k occurring between i and j in the linear order are dominated by i (where dominance is the transitive closure of the arc relation).

2.2 Global, Exhaustive, Graph-Based Parsing

For an input sentence, $x = w_0, w_1, \ldots, w_n$ consider the dense graph $G_x = (V_x, A_x)$ where:

1. $V_x = \{0, 1, \ldots, n\}$
2. $A_x = \{(i, j, l) \mid \forall\, i, j \in V_x \text{ and } l \in L\}$

Let $D(G_x)$ represent the subgraphs of graph G_x that are valid dependency graphs for the sentence x. Since G_x contains all possible labeled arcs, the set $D(G_x)$ must necessarily contain all valid dependency graphs for x.

Assume that there exists a dependency arc scoring function, $s : V \times V \times L \to \mathbb{R}$. Furthermore, define the score of a graph as the sum of its arc scores,

$$s(G = (V, A)) = \sum_{(i,j,l) \in A} s(i, j, l)$$

The score of a dependency arc, $s(i, j, l)$ represents the likelihood of creating a dependency from word w_i to word w_j with the label l. If the arc score function is known a priori, then the parsing problem can be stated as,

$$G = \underset{G \in D(G_x)}{\arg\max}\, s(G) = \underset{G \in D(G_x)}{\arg\max} \sum_{(i,j,l) \in A} s(i,j,l)$$

This problem is equivalent to finding the highest scoring directed spanning tree in the graph G_x originating out of the root node 0, which can be solved for both the labeled and unlabeled case in $O(n^2)$ time (McDonald et al., 2005b). In this approach, non-projective arcs are produced naturally through the inference algorithm that searches over all possible directed trees, whether projective or not.

The parsing models of McDonald work primarily in this framework. To learn arc scores, these models use large-margin structured learning algorithms (McDonald et al., 2005a), which optimize the parameters of the model to maximize the score margin between the correct dependency graph and all incorrect dependency graphs for every sentence in a training set. The learning procedure is global since model parameters are set relative to the classification of the entire dependency graph, and not just over single arc attachment decisions. The primary disadvantage of these models is that the feature representation is restricted to a limited number of graph arcs. This restriction is required so that both inference and learning are tractable.

The specific model studied in this work is that presented by McDonald et al. (2006), which factors scores over pairs of arcs (instead of just single arcs) and uses near exhaustive search for unlabeled parsing coupled with a separate classifier to label each arc. We call this system MSTParser, which is also the name of the freely available implementation.[1]

2.3 Local, Greedy, Transition-Based Parsing

A *transition system* for dependency parsing defines

1. a set C of *parser configurations*, each of which defines a (partially built) dependency graph G
2. a set T of *transitions*, each a function $t : C \rightarrow C$
3. for every sentence $x = w_0, w_1, \ldots, w_n$,
   (a) a unique *initial* configuration c_x
   (b) a set C_x of *terminal* configurations

A *transition sequence* $C_{x,m} = (c_x, c_1, \ldots, c_m)$ for a sentence x is a sequence of configurations such that $c_m \in C_x$ and, for every c_i ($c_i \neq c_x$), there is a transition $t \in T$ such that $c_i = t(c_{i-1})$. The dependency graph assigned to x by $C_{x,m}$ is the graph G_m defined by the terminal configuration c_m.

Assume that there exists a transition scoring function, $s : C \times T \rightarrow \mathbb{R}$. The score of a transition t in a configuration c, $s(c,t)$, represents the likelihood of taking transition t out of configuration c. The parsing problem consists in finding a terminal configuration $c_m \in C_x$, starting from the initial configuration c_x and taking the optimal transition $t^* = \arg\max_{t \in T} s(c,t)$ out of every configuration c. This can be seen as a greedy search for the optimal dependency graph, based on a sequence of locally optimal decisions in terms of the transition system.

Many transition systems for data-driven dependency parsing are inspired by shift-reduce parsing, where configurations contain a stack for storing partially processed nodes. Transitions in such systems add arcs to the dependency graph and/or manipulate the stack. One example is the transition system defined by Nivre (2003), which parses a sentence $x = w_0, w_1, \ldots, w_n$ in $O(n)$ time, producing a projective dependency graph satisfying conditions 1–4 in section 2.1, possibly after adding arcs $(0, i, l_r)$ for every node $i \neq 0$ that is a root in the output graph (where l_r is a special label for root modifiers). Nivre and Nilsson (2005) showed how the restriction to projective dependency graphs could be lifted by using graph transformation techniques to preprocess training data and post-process parser output, so-called *pseudo-projective parsing*.

To learn transition scores, these systems use discriminative learning methods, e.g., memory-based learning or support vector machines. The learning procedure is local since only single transitions are scored, not entire transition sequences. The primary advantage of these models is that features are not restricted to a limited number of graph arcs but can take into account the entire dependency graph built so far. The main disadvantage is that the greedy parsing strategy may lead to error propagation.

The specific model studied in this work is that presented by Nivre et al. (2006), which uses labeled pseudo-projective parsing with support vector machines. We call this system MaltParser, which is also

[1] http://mstparser.sourceforge.net

the name of the freely available implementation.[2]

2.4 Comparison

These models differ primarily with respect to three important properties.

1. **Inference:** MaltParser uses a transition-based inference algorithm that greedily chooses the best parsing decision based on a trained classifier and current parser history. MSTParser instead uses near exhaustive search over a dense graphical representation of the sentence to find the dependency graph that maximizes the score.

2. **Training:** MaltParser trains a model to make a single classification decision (choose the next transition). MSTParser trains a model to maximize the global score of correct graphs.

3. **Feature Representation:** MaltParser can introduce a rich feature history based on previous parser decisions. MSTParser is forced to restrict the score of features to a single or pair of nearby parsing decisions in order to make exhaustive inference tractable.

These differences highlight an inherent trade-off between exhaustive inference algorithms plus global learning and expressiveness of feature representations. MSTParser favors the former at the expense of the latter and MaltParser the opposite.

3 The CoNLL-X Shared Task

The CoNLL-X shared task (Buchholz and Marsi, 2006) was a large-scale evaluation of data-driven dependency parsers, with data from 13 different languages and 19 participating systems. The official evaluation metric was the *labeled attachment score* (LAS), defined as the percentage of tokens, excluding punctuation, that are assigned both the correct head and the correct dependency label.[3]

The output of all systems that participated in the shared task are available for download and constitute a rich resource for comparative error analysis. The data used in the experiments below are the outputs of MSTParser and MaltParser for all 13 languages, together with the corresponding gold standard graphs used in the evaluation. We constructed the data by simply concatenating a system's output for every language. This resulted in a single output file for each system and a corresponding single gold standard file. This method is sound because the data sets for each language contain approximately the same number of tokens – 5,000. Thus, evaluating system performance over the aggregated files can be roughly viewed as measuring system performance through an equally weighted arithmetic mean over the languages.

It could be argued that a language by language comparison would be more appropriate than comparing system performance across all languages. However, as table Table 1 shows, the difference in accuracy between the two systems is typically small for all languages, and only in a few cases is this difference significant. Furthermore, by aggregating over all languages we gain better statistical estimates of parser errors, since the data set for each individual language is very small.

4 Error Analysis

The primary purpose of this study is to characterize the errors made by standard data-driven dependency parsing models. To that end, we present a large set of experiments that relate parsing errors to a set of linguistic and structural properties of the input and predicted/gold standard dependency graphs. We argue that the results can be correlated to specific theoretical aspects of each model – in particular the trade-off highlighted in Section 2.4.

For simplicity, all experiments report labeled parsing accuracies. Identical experiments using unlabeled parsing accuracies did not reveal any additional information. Furthermore, all experiments are based on the data from all 13 languages together, as explained in section 3.

4.1 Length Factors

It is well known that parsing systems tend to have lower accuracies for longer sentences. Figure 2 shows the accuracy of both parsing models relative to sentence length (in bins of size 10: 1–10, 11–20,

[2] http://w3.msi.vxu.se/users/nivre/research/MaltParser.html

[3] In addition, results were reported for *unlabeled attachment score* (UAS) (tokens with the correct head) and *label accuracy* (LA) (tokens with the correct label).

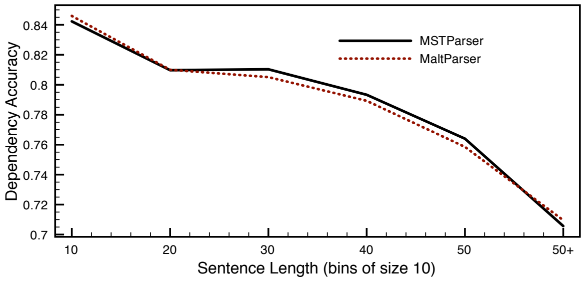

Figure 2: Accuracy relative to sentence length.

etc.). System performance is almost indistinguishable. However, MaltParser tends to perform better on shorter sentences, which require the greedy inference algorithm to make less parsing decisions. As a result, the chance of error propagation is reduced significantly when parsing these sentences. The fact that MaltParser has a higher accuracy (rather than the same accuracy) when the likelihood of error propagation is reduced comes from its richer feature representation.

Another interesting property is accuracy relative to dependency length. The length of a dependency from word w_i to word w_j is simply equal to $|i - j|$. Longer dependencies typically represent modifiers of the root or the main verb in a sentence. Shorter dependencies are often modifiers of nouns such as determiners or adjectives or pronouns modifying their direct neighbours. Figure 3 measures the precision and recall for each system relative to dependency lengths in the predicted and gold standard dependency graphs. Precision represents the percentage of predicted arcs of length d that were correct. Recall measures the percentage of gold standard arcs of length d that were correctly predicted.

Here we begin to see separation between the two systems. MSTParser is far more precise for longer dependency arcs, whereas MaltParser does better for shorter dependency arcs. This behaviour can be explained using the same reasoning as above: shorter arcs are created before longer arcs in the greedy parsing procedure of MaltParser and are less prone to error propagation. Theoretically, MSTParser should not perform better or worse for edges of any length, which appears to be the case. There is still a slight degradation, but this can be attributed to long dependencies occurring more frequently in constructions with possible ambiguity. Note that even though the area under the curve is much larger for MSTParser, the number of dependency arcs with a length greater than ten is much smaller than the number with length less than ten, which is why the overall accuracy of each system is nearly identical. For all properties considered here, bin size generally shrinks in size as the value on the x-axis increases.

4.2 Graph Factors

The structure of the predicted and gold standard dependency graphs can also provide insight into the differences between each model. For example, measuring accuracy for arcs relative to their distance to the artificial root node will detail errors at different levels of the dependency graph. For a given arc, we define this distance as the number of arcs in the reverse path from the modifier of the arc to the root. Figure 4 plots the precision and recall of each system for arcs of varying distance to the root. Precision is equal to the percentage of dependency arcs in the predicted graph that are at a distance of d and are correct. Recall is the percentage of dependency arcs in the gold standard graph that are at a distance of d and were predicted.

Figure 4 clearly shows that for arcs close to the root, MSTParser is much more precise than MaltParser, and vice-versa for arcs further away from the root. This is probably the most compelling graph given in this study since it reveals a clear distinction: MSTParser's precision degrades as the distance to the root increases whereas MaltParser's precision increases. The plots essentially run in opposite directions crossing near the middle. Dependency arcs further away from the root are usually constructed early in the parsing algorithm of MaltParser. Again a reduced likelihood of error propagation coupled with a rich feature representation benefits that parser substantially. Furthermore, MaltParser tends to overpredict root modifiers, because all words that the parser fails to attach as modifiers are automatically connected to the root, as explained in section 2.3. Hence, low precision for root modifiers (without a corresponding drop in recall) is an indication that the transition-based parser produces fragmented parses.

The behaviour of MSTParser is a little trickier to explain. One would expect that its errors should be distributed evenly over the graph. For the most part this is true, with the exception of spikes at the ends

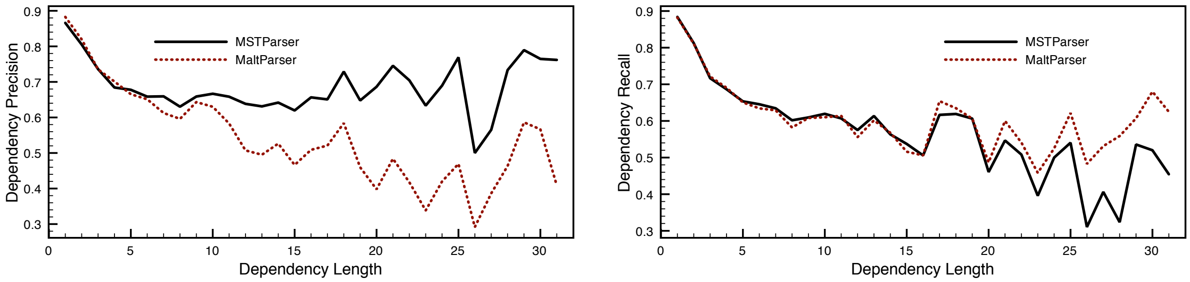

Figure 3: Dependency arc precision/recall relative to predicted/gold dependency length.

of the plot. The high performance for root modification (distance of 1) can be explained through the fact that this is typically a low entropy decision – usually the parsing algorithm has to determine the main verb from a small set of possibilities. On the other end of the plot there is a sharp downwards spike for arcs of distance greater than 10. It turns out that MSTParser over-predicts arcs near the bottom of the graph. Whereas MaltParser pushes difficult parsing decisions higher in the graph, MSTParser appears to push these decisions lower.

The next graph property we will examine aims to quantify the local neighbourhood of an arc within a dependency graph. Two dependency arcs, (i, j, l) and (i', j', l') are classified as siblings if they represent syntactic modifications of the same word, i.e., $i = i'$. Figure 5 measures the precision and recall of each system relative to the number of predicted and gold standard siblings of each arc. There is not much to distinguish between the parsers on this metric. MSTParser is slightly more precise for arcs that are predicted with more siblings, whereas MaltParser has slightly higher recall on arcs that have more siblings in the gold standard tree. Arcs closer to the root tend to have more siblings, which ties this result to the previous ones.

The final graph property we wish to look at is the degree of non-projectivity. The degree of a dependency arc from word w to word u is defined here as the number of words occurring between w and u that are not descendants of w and modify a word that does not occur between w and u (Nivre, 2006). In the example from Figure 1, the arc from *jedna* to *Z* has a degree of one, and all other arcs have a degree of zero. Figure 6 plots dependency arc precision and recall relative to arc degree in predicted and gold standard dependency graphs. MSTParser is more precise when predicting arcs with high degree and MaltParser vice-versa. Again, this can be explained by the fact that there is a tight correlation between a high degree of non-projectivity, dependency length, distance to root and number of siblings.

4.3 Linguistic Factors

It is important to relate each system's accuracy to a set of linguistic categories, such as parts of speech and dependency types. Therefore, we have made an attempt to distinguish a few broad categories that are cross-linguistically identifiable, based on the available documentation of the treebanks used in the shared task.

For parts of speech, we distinguish *verbs* (including both main verbs and auxiliaries), *nouns* (including proper names), *pronouns* (sometimes also including determiners), *adjectives*, *adverbs*, *adpositions* (prepositions, postpositions), and *conjunctions* (both coordinating and subordinating). For dependency types, we distinguish a general *root* category (for labels used on arcs from the artificial root, including either a generic label or the label assigned to predicates of main clauses, which are normally verbs), a *subject* category, an *object* category (including both direct and indirect objects), and various categories related to *coordination*.

Figure 7 shows the accuracy of the two parsers for different parts of speech. This figure measures labeled dependency accuracy relative to the part of speech of the modifier word in a dependency relation. We see that MaltParser has slightly better accuracy for nouns and pronouns, while MSTParser does better on all other categories, in particular conjunctions. This pattern is consistent with previous results insofar as verbs and conjunctions are often involved in dependencies closer to the root that span

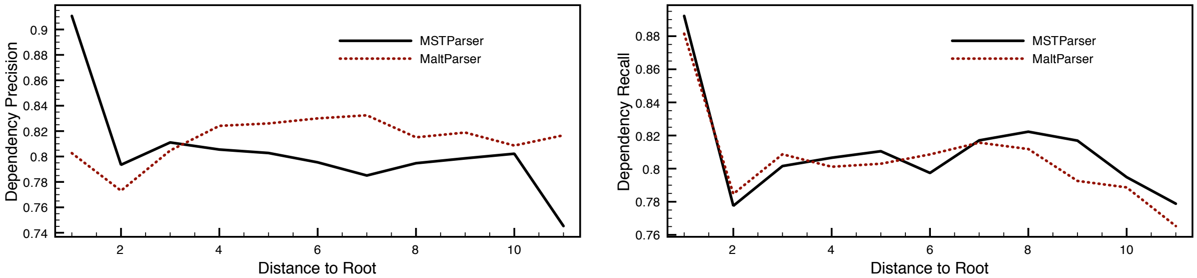

Figure 4: Dependency arc precision/recall relative to predicted/gold distance to root.

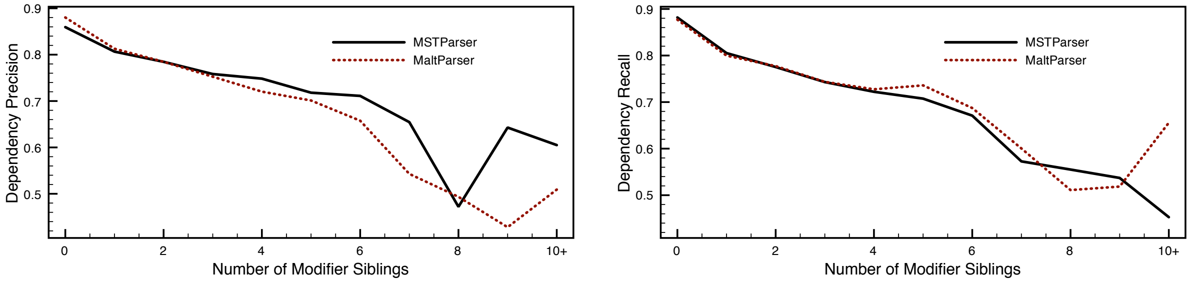

Figure 5: Dependency arc precision/recall relative to number of predicted/gold siblings.

longer distances, while nouns and pronouns are typically attached to verbs and therefore occur lower in the graph, with shorter distances. Empirically, adverbs resemble verbs and conjunctions with respect to root distance but group with nouns and pronouns for dependency length, so the former appears to be more important. In addition, both conjunctions and adverbs tend to have a high number of siblings, making the results consistent with the graph in Figure 5.

Adpositions and especially adjectives constitute a puzzle, having both high average root distance and low average dependency length. Adpositions do tend to have a high number of siblings on average, which could explain MSTParser's performance on that category. However, adjectives on average occur the furthest away from the root, have the shortest dependency length and the fewest siblings. As such, we do not have an explanation for this behaviour.

In the top half of Figure 8, we consider precision and recall for dependents of the root node (mostly verbal predicates), and for subjects and objects. As already noted, MSTParser has considerably better precision (and slightly better recall) for the root category, but MaltParser has an advantage for the nominal categories, especially subjects. A possible explanation for the latter result, in addition to the length-based and graph-based factors invoked before, is that MaltParser integrates labeling into the parsing process, so that previously assigned dependency labels can be used as features, which may be important to disambiguate subjects and objects.

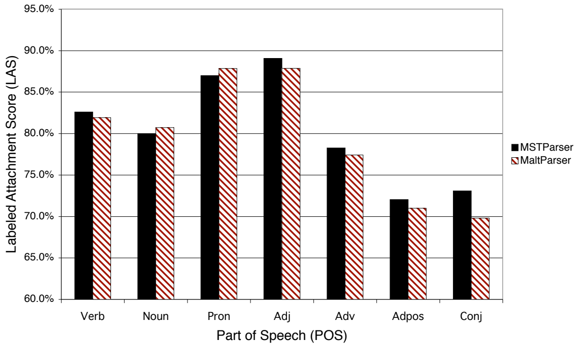

Figure 7: Accuracy for different parts of speech.

Finally, in the bottom half of Figure 8, we display precision and recall for coordinate structures, divided into different groups depending on the type of analysis adopted in a particular treebank. The category CCH (coordinating conjunction as head) contains conjunctions analyzed as heads of coordinate structures, with a special dependency label that does not describe the function of the coordinate structure in the larger syntactic structure, a type of category found in the so-called Prague style analysis of coordination and used in the data sets for Arabic, Czech,

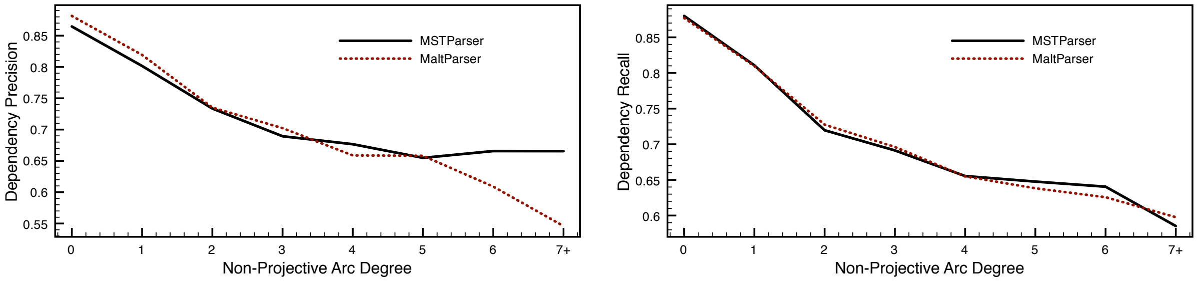

Figure 6: Dependency arc precision/recall relative to predicted/gold degree of non-projectivity.

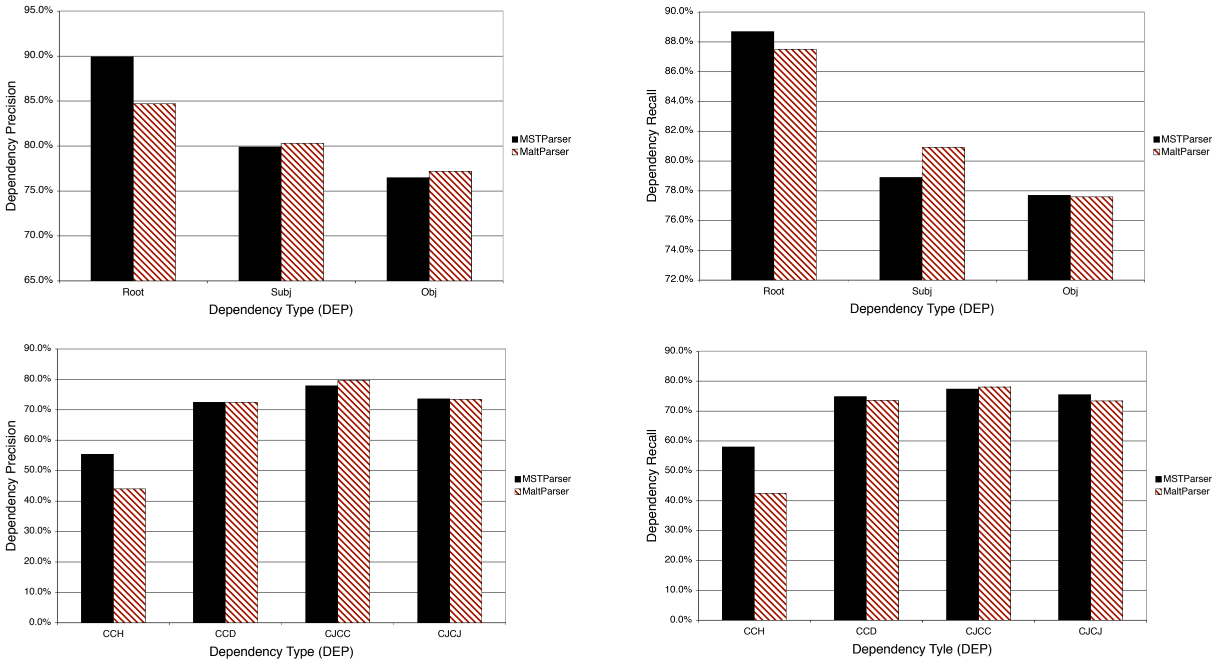

Figure 8: Precision/recall for different dependency types.

and Slovene. The category CCD (coordinating conjunction as dependent) instead denotes conjunctions that are attached as dependents of one of the conjuncts with a label that only marks them as conjunctions, a type of category found in the data sets for Bulgarian, Danish, German, Portuguese, Swedish and Turkish. The two remaining categories contain conjuncts that are assigned a dependency label that only marks them as conjuncts and that are attached either to the conjunction (CJCC) or to another conjunct (CJCJ). The former is found in Bulgarian, Danish, and German; the latter only in Portuguese and Swedish. For most of the coordination categories there is little or no difference between the two parsers, but for CCH there is a difference in both precision and recall of almost 20 percentage points to MSTParser's advantage. This can be explained by noting that, while the categories CCD, CJCC, and CJCJ denote relations that are *internal* to the coordinate structure and therefore tend to be local, the CCH relations hold between the coordinate structure and its head, which is often a relation that spans over a greater distance and is nearer the root of the dependency graph. It is likely that the difference in accuracy for this type of dependency accounts for a large part of the difference in accuracy noted earlier for conjunctions as a part of speech.

4.4 Discussion

The experiments from the previous section highlight the fundamental trade-off between global training and exhaustive inference on the one hand and expressive feature representations on the other. Error propagation is an issue for MaltParser, which typically performs worse on long sentences, long dependency arcs and arcs higher in the graphs. But this is offset by the rich feature representation available to these models that result in better decisions for frequently occurring arc types like short dependencies or subjects and objects. The errors for MSTParser are spread a little more evenly. This is expected, as the inference algorithm and feature representation should not prefer one type of arc over another.

What has been learned? It was already known that the two systems make different errors through the work of Sagae and Lavie (2006). However, in that work an arc-based voting scheme was used that took only limited account of the properties of the words connected by a dependency arc (more precisely, the overall accuracy of each parser for the part of speech of the dependent). The analysis in this work not only shows that the errors made by each system are different, but that they are different in a way that can be predicted and quantified. This is an important step in parser development.

To get some upper bounds of the improvement that can be obtained by combining the strengths of each models, we have performed two oracle experiments. Given the output of the two systems, we can envision an oracle that can optimally choose which single parse or combination of sub-parses to predict as a final parse. For the first experiment the oracle is provided with the single best parse from each system, say $G = (V, A)$ and $G' = (V', A')$. The oracle chooses a parse that has the highest number of correctly predicted labeled dependency attachments. In this situation, the oracle accuracy is 84.5%. In the second experiment the oracle chooses the tree that maximizes the number of correctly predicted dependency attachments, subject to the restriction that the tree must only contain arcs from $A \cup A'$. This can be computed by setting the weight of an arc to 1 if it is in the correct parse and in the set $A \cup A'$. All other arc weights are set to negative infinity. One can then simply find the tree that has maximal sum of arc weights using directed spanning tree algorithms. This technique is similar to the parser voting methods used by Sagae and Lavie (2006). In this situation, the oracle accuracy is 86.9%.

In both cases we see a clear increase in accuracy: 86.9% and 84.5% relative to 81% for the individual systems. This indicates that there is still potential for improvement, just by combining the two existing models. More interestingly, however, we can use the analysis to get ideas for new models. Below we sketch some possible new directions:

1. **Ensemble systems:** The error analysis presented in this paper could be used as inspiration for more refined weighting schemes for ensemble systems of the kind proposed by Sagae and Lavie (2006), making the weights depend on a range of linguistic and graph-based factors.

2. **Hybrid systems:** Rather than using an ensemble of several parsers, we may construct a single system integrating the strengths of each parser described here. This could defer to a greedy inference strategy during the early stages of the parse in order to benefit from a rich feature representation, but then default to a global exhaustive model as the likelihood for error propagation increases.

3. **Novel approaches:** The two approaches investigated are each based on a particular combination of training and inference methods. We may naturally ask what other combinations may prove fruitful. For example, what about globally trained, greedy, transition-based models? This is essentially what Daumé III et al. (2006) provide, in the form of a general search-based structured learning framework that can be directly applied to dependency parsing. The advantage of this method is that the learning can set model parameters relative to errors resulting directly from the search strategy – such as error propagation due to greedy search. When combined with MaltParser's rich feature representation, this could lead to significant improvements in performance.

5 Conclusion

We have presented a thorough study of the difference in errors made between global exhaustive graph-based parsing systems (MSTParser) and local greedy transition-based parsing systems (MaltParser). We have shown that these differences can be quantified and tied to theoretical expectations of each model, which may provide insights leading to better models in the future.

Abstract

A notable gap in research on statistical dependency parsing is a proper conditional probability distribution over nonprojective dependency trees for a given sentence. We exploit the Matrix Tree Theorem (Tutte, 1984) to derive an algorithm that efficiently sums the scores of all nonprojective trees in a sentence, permitting the definition of a conditional log-linear model over trees. While discriminative methods, such as those presented in McDonald et al. (2005b), obtain very high accuracy on standard dependency parsing tasks and can be trained and applied without marginalization, "summing trees" permits some alternative techniques of interest. Using the summing algorithm, we present competitive experimental results on four nonprojective languages, for maximum conditional likelihood estimation, minimum Bayes-risk parsing, and hidden variable training.

1 Introduction

Recently dependency parsing has received renewed interest, both in the parsing literature (Buchholz and Marsi, 2006) and in applications like translation (Quirk et al., 2005) and information extraction (Culotta and Sorensen, 2004). Dependency parsing can be used to provide a "bare bones" syntactic structure that approximates semantics, and it has the additional advantage of admitting fast parsing algorithms (Eisner, 1996; McDonald et al., 2005b) with a negligible grammar constant in many cases.

The latest state-of-the-art statistical dependency parsers are **discriminative**, meaning that they are based on classifiers trained to score trees, given a sentence, either via factored whole-structure scores (McDonald et al., 2005a) or local parsing decision scores (Hall et al., 2006). In the works cited, these scores are not intended to be interpreted as probabilistic quantities.

Here we consider weighted dependency parsing models that can be used to define well-formed conditional distributions $p(\mathbf{y} \mid \mathbf{x})$, for dependency trees $\mathbf{y}$ and a sentence $\mathbf{x}$. Conditional distributions over outputs (here, trees) given inputs (here, sentences) have certain advantages. They permit marginalization over trees to compute **posteriors** of interesting sub-events (e.g., the probability that two noun tokens bear a relation, regardless of which tree is correct). A probability model permits alternative **decoding** procedures (Goodman, 1996). Well-motivated **hidden variable** training procedures (such as EM and conditional EM) are also readily available for probabilistic models. Finally, probability models can be chained together (as in a noisy channel model), mixed, or combined in a product-of-experts.

Sequence models, context-free models, and dependency models have appeared in several guises; a cross-model comparison clarifies the contribution of this paper. First, there were generative, stochastic models like HMMs, PCFGs, and Eisner's (1996) models. Local discriminative classifiers were proposed by McCallum et al. (2000) for sequence modeling, by Ratnaparkhi et al. (1994) for constituent parsing, and by Hall et al. (2006) (among others) for

Proceedings of the 2007 Joint Conference on Empirical Methods in Natural Language Processing and Computational Natural Language Learning, pp. 132–140, Prague, June 2007.

dependencies. Large-margin whole-structure models were proposed for sequence labeling by Altun et al. (2003), for constituents by Taskar et al. (2004), and for dependency trees by McDonald et al. (2005a). In this paper, we propose a model most similar to the conditional random fields—interpretable as log-linear models—of Lafferty et al. (2001), which are now widely used for sequence labeling. Log-linear models have been used in parsing by Riezler et al. (2000) (for constraint-based grammars) and Johnson (2001) and Miyao and Tsujii (2002) (for CFGs). Like McDonald et al., we use an edge-factored model that permits *nonprojective* trees; like Lafferty et al., we argue for an alternative interpretation as a **log-linear model** over structures, conditioned on the observed sentence.

In Section 2 we point out what would be required, computationally, for conditional training of nonprojective dependency models. The solution to the conditionalization problem is given in Section 3, using a widely-known but newly-applied Matrix Tree Theorem due to Tutte (1984), and experimental results are presented with a comparison to the MIRA learning algorithm used by McDonald et al. (2005a). We go on to describe and experiment with two useful applications of conditional modeling: minimum Bayes-risk decoding (Section 4) and hidden-variable training by conditional maximum likelihood estimation (Section 5). Discussion in Section 6 considers the implications of our experimental results.

Two indepedent papers, published concurrently with this one, report closely related results to ours. Koo et al. (2007) and McDonald and Satta (2007) both describe how the Matrix Tree Theorem can be applied to computing the sum of scores of edge-factored dependency trees and the edge marginals. Koo et al. compare conditional likelihood training (as here) to the averaged perceptron and a maximum margin model trained using exponentiated-gradient (Bartlett et al., 2004); the latter requires the same marginalization calculations as conditional log-linear estimation. McDonald and Satta discuss a variety of applications (including minimum Bayes-risk decoding) and give complexity results for non-edge-factored models. Interested readers are referred to those papers for further discussion.

2 Conditional Training for Nonprojective Dependency Models

Let $\mathbf{x} = \langle x_1, ..., x_n \rangle$ be a sequence of words (possibly with POS tags, lemmas, and morphological information) that are the input to a parser. $\mathbf{y}$ will refer to a directed, unlabeled dependency tree, which is a map $\mathbf{y} : \{1, ..., n\} \to \{0, ..., n\}$ from child indices to parent indices; x_0 is the invisible "wall" symbol. Let $\mathcal{Y}_\mathbf{x}$ be the set of valid dependency trees for $\mathbf{x}$. In this paper, $\mathcal{Y}_\mathbf{x}$ is equivalent to the set of all directed spanning trees over $\mathbf{x}$.[1]

A conditional model defines a family of probability distributions $p(\mathbf{y} \mid \mathbf{x})$, for all $\mathbf{x}$ and $\mathbf{y} \in \mathcal{Y}_\mathbf{x}$. We propose that this model take a log-linear form:

$$p_{\vec{\theta}}(\mathbf{y} \mid \mathbf{x}) = \frac{e^{\vec{\theta} \cdot \vec{f}(\mathbf{x},\mathbf{y})}}{\sum_{\mathbf{y}' \in \mathcal{Y}_\mathbf{x}} e^{\vec{\theta} \cdot \vec{f}(\mathbf{x},\mathbf{y}')}} = \frac{e^{\vec{\theta} \cdot \vec{f}(\mathbf{x},\mathbf{y})}}{Z_{\vec{\theta}}(\mathbf{x})} \qquad (1)$$

where $\vec{f}$ is a feature vector function on parsed sentences and $\vec{\theta} \in \mathbb{R}^m$ parameterizes the model. Following McDonald et al. (2005a), we assume that the features are **edge-factored**:

$$\vec{f}(\mathbf{x}, \mathbf{y}) = \sum_{i=1}^{n} \vec{f}(\mathbf{x}, x_i, x_{\mathbf{y}(i)}) \qquad (2)$$

In other words, the dependencies between words in the tree are all conditionally independent of each other, given the sequence $\mathbf{x}$ and the fact that the parse is a spanning tree. Despite the constraints they impose on features, edge-factored models have the advantage of tractable $O(n^3)$ inference algorithms or, with some trickery, $O(n^2)$ maximum *a posteriori* ("best parse tree") inference algorithms in the nonprojective case. Exact nonprojective inference and estimation become intractable if we break edge factoring (McDonald and Pereira, 2006).

We wish to estimate the parameters $\vec{\theta}$ by maximizing the conditional likelihood (like a CRF) rather

[1] To be precise, every word has in-degree 1, with the sole edge pointing from the word's parent, $x_{\mathbf{y}(i)} \to x_i$. x_0 has in-degree 0. By definition, trees are acyclic. The edges need not be planar and may "cross" in the plane, since we do not have a projectivity constraint. In some formulations, exactly one node in $\mathbf{x}$ can attach to x_0; here we allow multiple nodes to attach to x_0, since this occurs with some frequency in many existing datasets. Summation over trees where x_0 has exactly one child is addressed directly by Koo et al. (2007).

than the margin (McDonald et al., 2005a). For an empirical distribution $\tilde{p}$ given by a set of training examples, this means:

$$\max_{\vec{\theta}} \sum_{\mathbf{x},\mathbf{y}} \tilde{p}(\mathbf{x},\mathbf{y}) \left(\vec{\theta}\cdot\vec{f}(\mathbf{x},\mathbf{y})\right) - \sum_{\mathbf{x}} \tilde{p}(\mathbf{x}) \log Z_{\vec{\theta}}(\mathbf{x}) \tag{3}$$

This optimization problem is typically solved using a quasi-Newton numerical optimization method such as L-BFGS (Liu and Nocedal, 1989). Such a method requires the gradient of the objective function, which for θ_k is given by the following difference in expectations of the value of feature f_k:

$$\frac{\partial}{\partial\theta_k} = \mathbf{E}_{\tilde{p}(\mathbf{X},\mathbf{Y})}\left[f_k(\mathbf{X},\mathbf{Y})\right] - \mathbf{E}_{\tilde{p}(\mathbf{X})p_{\vec{\theta}}(\mathbf{Y}|\mathbf{X})}\left[f_k(\mathbf{X},\mathbf{Y})\right] \tag{4}$$

The computation of $Z_{\vec{\theta}}(\mathbf{x})$ and the sufficient statistics (second expectation in Equation 4) are typically the difficult parts. They require summing the scores of all the spanning trees for a given sentence. Note that, in large-margin training, and in standard maximum *a posteriori* decoding, only a *maximum* over spanning trees is called for—it is *conditional training* that requires $Z_{\vec{\theta}}(\mathbf{x})$. In Section 3, we will show how this can be done exactly in $O(n^3)$ time.

3 Exploiting the Matrix Tree Theorem for $Z_{\vec{\theta}}(\mathbf{x})$

We wish to apply conditional training to estimate conditional models of nonprojective trees. This requires computing $Z_{\vec{\theta}}(\mathbf{x})$ for each training example (as an inner loop to training). In this section we show how the summation can be computed and how conditional training performs.

3.1 Kirchoff Matrix

Recall that we defined the unnormalized probability (henceforth, **score**) of a dependency tree as a combination of edge-factored scores for the edges present in the tree (Eq. 2):

$$\exp \vec{\theta}\cdot\vec{f}(\mathbf{x},\mathbf{y}) = \prod_{i=1}^{n} e^{\vec{\theta}\cdot\vec{f}(\mathbf{x},x_i,x_{\mathbf{y}(i)})} = \prod_{i=1}^{n} s_{\mathbf{x},\vec{\theta}}(i,\mathbf{y}(i)) \tag{5}$$

where $\mathbf{y}(i)$ denotes the parent of x_i in $\mathbf{y}$. $s_{\mathbf{x},\vec{\theta}}(i,j)$, then, denotes the (multiplicative) contribution of the edge from child i to parent j to the total score of the tree, if the edge is present. Define the **Kirchoff matrix** $\mathbf{K}_{\mathbf{x},\vec{\theta}} \in \mathbb{R}^{n\times n}$ by

$$\left[\mathbf{K}_{\mathbf{x},\vec{\theta}}\right]_{mom,kid} = \begin{cases} -s_{\mathbf{x},\vec{\theta}}(kid,mom) & \text{if } mom \neq kid \\ \sum\limits_{j\in\{0,\ldots n\}:j\neq mom} s_{\mathbf{x},\vec{\theta}}(kid,j) & \text{if } mom = kid. \end{cases} \tag{6}$$

where mom indexes a parent node and kid a child node.

$\mathbf{K}_{\mathbf{x}\vec{\theta}}$ can be regarded as a special weighted adjacency matrix in which the ith diagonal entry is the sum of edge-scores directed into vertex i (i.e., x_i is the child)—note that the sum includes the score of attaching x_i to the wall x_0.

In our notation and in one specific form, the Matrix Tree Theorem (Tutte, 1984) states:[2]

Theorem 1 *The determinant of the Kirchoff matrix* $\mathbf{K}_{\mathbf{x},\vec{\theta}}$ *is equal to the sum of scores of all directed spanning trees in* $\mathcal{Y}_{\mathbf{x}}$ *rooted at* x_0. *Formally:*

$$\left|\mathbf{K}_{\mathbf{x},\vec{\theta}}\right| = Z_{\vec{\theta}}(\mathbf{x}).$$

A proof is omitted; see Tutte (1984).

To compute $Z_{\vec{\theta}}(\mathbf{x})$, we need only take the determinant of $\mathbf{K}_{\mathbf{x},\vec{\theta}}$, which can be done in $O(n^3)$ time using the standard LU factorization to compute the matrix inverse. Since all of the edge weights used to construct the Kirchoff matrix are positive, it is diagonally dominant and therefore non-singular (i.e., invertible).

3.2 Gradient

The gradient of $Z_{\vec{\theta}}(\mathbf{x})$ (required for numerical optimization; see Eqs. 3–4) can be efficiently computed from the same matrix inverse. While $\nabla \log Z_{\vec{\theta}}(\mathbf{x})$ equates to a vector of feature expectations (Eq. 4), we exploit instead some facts from linear algebra

[2] There are proven generalizations of this theorem (Chen, 1965; Chaiken, 1982; Minoux, 1999); we give the most specific form that applies to our case, originally proved by Tutte in 1948. Strictly speaking, our $\mathbf{K}_{\mathbf{x},\vec{\theta}}$ is not the Kirchoff matrix, but rather a *submatrix* of the Kirchoff matrix with a leftmost column of zeroes and a topmost row $[0, -s_{\mathbf{x},\vec{\theta}}(1,0), \ldots, -s_{\mathbf{x},\vec{\theta}}(n,0)]$ removed. Farther afield, Jaakkola et al. (1999) used an undirected matrix tree theorem for learning tree structures for graphical models.

$$\mathbf{K}_{\mathbf{x},\vec{\theta}} = \begin{bmatrix} \sum\limits_{j \in \{0,\ldots,n\}: j \neq 1} s_{\mathbf{x},\vec{\theta}}(1,j) & -s_{\mathbf{x},\vec{\theta}}(2,1) & \cdots & -s_{\mathbf{x},\vec{\theta}}(n,1) \\ -s_{\mathbf{x},\vec{\theta}}(1,2) & \sum\limits_{j \in \{0,\ldots,n\}: j \neq 2} s_{\mathbf{x},\vec{\theta}}(2,j) & \cdots & -s_{\mathbf{x},\vec{\theta}}(n,2) \\ \vdots & \vdots & \ddots & \vdots \\ -s_{\mathbf{x},\vec{\theta}}(1,n) & -s_{\mathbf{x},\vec{\theta}}(2,n) & \cdots & \sum\limits_{j \in \{0,\ldots,n\}: j \neq n} s_{\mathbf{x},\vec{\theta}}(n,j) \end{bmatrix}$$

and the chain rule. First, note that, for any weight θ_k,

$$\begin{aligned} & \frac{\partial \log Z_{\vec{\theta}}(\mathbf{x})}{\partial \theta_k} \\ &= \frac{\partial \log |\mathbf{K}_{\mathbf{x},\vec{\theta}}|}{\partial \theta_k} \\ &= \frac{1}{|\mathbf{K}_{\mathbf{x},\vec{\theta}}|} \frac{\partial |\mathbf{K}_{\mathbf{x},\vec{\theta}}|}{\partial \theta_k} \\ &= \frac{1}{|\mathbf{K}_{\mathbf{x},\vec{\theta}}|} \sum_{i=1}^{n} \sum_{j=0}^{n} \frac{\partial |\mathbf{K}_{\mathbf{x},\vec{\theta}}|}{\partial s_{\mathbf{x},\vec{\theta}}(i,j)} \frac{\partial s_{\mathbf{x},\vec{\theta}}(i,j)}{\partial \theta_k} \\ &= \frac{1}{|\mathbf{K}_{\mathbf{x},\vec{\theta}}|} \sum_{i=1}^{n} \sum_{j=0}^{n} s_{\mathbf{x},\vec{\theta}}(i,j) f_k(\mathbf{x}, x_i, x_j) \\ & \qquad \times \frac{\partial |\mathbf{K}_{\mathbf{x},\vec{\theta}}|}{\partial s_{\mathbf{x},\vec{\theta}}(i,j)} \end{aligned} \tag{7}$$

(We assume $s_{\mathbf{x},\vec{\theta}}(i,i) = 0$, for simplicity of notation.) The last line follows from the definition of $s_{\mathbf{x},\vec{\theta}}(i,j)$ as $\exp \vec{\theta} \cdot \vec{f}(\mathbf{x}, x_i, x_j)$. Now, since $s_{\mathbf{x},\vec{\theta}}(i,j)$ affects the Kirchoff matrix in *at most* two cells—(i,i) and (j,i), the latter only when $j > 0$—we know that

$$\begin{aligned} \frac{\partial |\mathbf{K}_{\mathbf{x},\vec{\theta}}|}{\partial s_{\mathbf{x},\vec{\theta}}(i,j)} &= \frac{\partial |\mathbf{K}_{\mathbf{x},\vec{\theta}}|}{\partial [\mathbf{K}_{\mathbf{x},\vec{\theta}}]_{i,i}} \frac{\partial [\mathbf{K}_{\mathbf{x},\vec{\theta}}]_{i,i}}{\partial s_{\mathbf{x},\vec{\theta}}(i,i)} \\ & \quad - \frac{\partial |\mathbf{K}_{\mathbf{x},\vec{\theta}}|}{\partial [\mathbf{K}_{\mathbf{x},\vec{\theta}}]_{j,i}} \frac{\partial [\mathbf{K}_{\mathbf{x},\vec{\theta}}]_{j,i}}{\partial s_{\mathbf{x},\vec{\theta}}(i,j)} \\ &= \frac{\partial |\mathbf{K}_{\mathbf{x},\vec{\theta}}|}{\partial [\mathbf{K}_{\mathbf{x},\vec{\theta}}]_{i,i}} - \frac{\partial |\mathbf{K}_{\mathbf{x},\vec{\theta}}|}{\partial [\mathbf{K}_{\mathbf{x},\vec{\theta}}]_{j,i}} \end{aligned} \tag{8}$$

We have now reduced the problem of the gradient to a linear function of $\nabla |\mathbf{K}_{\mathbf{x},\vec{\theta}}|$ with respect to the cells of the matrix itself. At this point, we simplify notation and consider an arbitrary matrix $\mathbf{A}$.

The minor $m_{j,i}$ of a matrix $\mathbf{A}$ is the determinant of the submatrix obtained by striking out row j and column i of $\mathbf{A}$; the cofactor $c_{j,i}$ of $\mathbf{A}$ is then $(-1)^{i+j} m_{j,i}$. Laplace's formula defines the determinant as a linear combination of matrix cofactors of an arbitrary row j:

$$|\mathbf{A}| = \sum_{i=1}^{n} [\mathbf{A}]_{j,i} c_{j,i} \tag{9}$$

It should be clear that any $c_{j,k}$ is constant with respect to the cell $[\mathbf{A}]_{j,i}$ (since it is formed by removing row j of $\mathbf{A}$) and that other entries of $\mathbf{A}$ are constant with respect to the cell $[\mathbf{A}]_{j,i}$. Therefore:

$$\frac{\partial |\mathbf{A}|}{\partial [\mathbf{A}]_{j,i}} = c_{j,i} \tag{10}$$

The inverse matrix $\mathbf{A}^{-1}$ can also be defined in terms of cofactors:

$$[\mathbf{A}^{-1}]_{i,j} = \frac{c_{j,i}}{|\mathbf{A}|} \tag{11}$$

Combining Eqs. 10 and 11, we have:

$$\frac{\partial |\mathbf{A}|}{\partial [\mathbf{A}]_{j,i}} = |\mathbf{A}| [\mathbf{A}^{-1}]_{i,j} \tag{12}$$

Plugging back in through Eq. 8 to Eq. 7, we have:

$$\begin{aligned} \frac{\partial \log Z_{\vec{\theta}}(\mathbf{x})}{\partial \theta_k} &= \sum_{i=1}^{n} \sum_{j=0}^{n} s_{\mathbf{x},\vec{\theta}}(i,j) f_k(\mathbf{x}, x_i, x_j) \\ & \quad \times \left(\left[\mathbf{K}_{\mathbf{x},\vec{\theta}}^{-1} \right]_{i,i} - \left[\mathbf{K}_{\mathbf{x},\vec{\theta}}^{-1} \right]_{i,j} \right) \end{aligned} \tag{13}$$

where $[\mathbf{K}^{-1}]_{i,0}$ is taken to be 0. Note that the cofactors do not need to be computed directly. We proposed in Section 3.1 to get $Z_{\vec{\theta}}(\mathbf{x})$ by computing the inverse of the Kirchoff matrix (which is known to exist). Under that procedure, the marginalization is a by-product of the gradient.

decode	train	Arabic	Czech	Danish	Dutch	
m*ap*	MIRA	79.9	**81.4**	86.6	**90.0**	
	CE	80.4	80.2	**87.5**	**90.0**	(Section 3)
mBr	MIRA	79.4	80.3	85.0	87.2	(Section 4)
	CE	**80.5**	80.4	**87.5**	**90.0**	(Sections 3 & 4)

Table 1: Unlabeled dependency parsing accuracy (on test data) for two training methods (MIRA, as in McDonald et al. (2005b), and conditional estimation) and with maximum *a posteriori* (m*ap*) and minimum Bayes-risk (mBr) decoding. **Boldface** scores are best in their column on a permutation test at the .05 level.

3.3 Experiment

We compare conditional training of a nonprojective edge-factored parsing model to the online MIRA training used by McDonald et al. (2005b). Four languages with relatively common nonprojective phenomena were tested: Arabic (Hajič et al., 2004), Czech (Böhmová et al., 2003), Danish (Kromann, 2003), and Dutch (van der Beek et al., 2002). The Danish and Dutch datasets were prepared for the CoNLL 2006 shared task (Buchholz and Marsi, 2006); Arabic and Czech are from the 2007 shared task. We used the same features, extracted by McDonald's code, in both MIRA and conditional training. In this paper, we consider only *unlabeled* dependency parsing.

Our conditional training used an online gradient-based method known as stochastic gradient descent (see, e.g., Bottou, 2003). Training with MIRA and conditional estimation take about the same amount of time: approximately 50 sentences per second. Training proceeded as long as an improvement on held-out data was evident. The accuracy of the hypothesized parses for the two models, on each language, are shown in the top two rows of Tab. 1 (labeled "m*ap*" for maximum *a posteriori*, meaning that the highest-weighted tree is hypothesized).

The two methods are, not surprisingly, close in performance; conditional likelihood outperformed MIRA on Arabic and Danish, underperformed MIRA on Czech, and the two tied on Dutch. Results are significant at the .05 level on a permutation test. Conditional estimation is in practice more prone to over-fitting than maximum margin methods, though we did not see any improvement using zero-mean Gaussian priors (variance 1 or 10).

These experiments serve to validate conditional estimation as a competitive learning algorithm for parsing models, and the key contribution of the summing algorithm that permits conditional estimation.

4 Minimum Bayes-Risk Decoding

A second application of probability distributions over trees is the alternative decoding algorithm known as **minimum Bayes-risk** (mBr) decoding. The more commonly used maximum *a posteriori* decoding (also known as "Viterbi" decoding) that we applied in Section 3.3 sought to minimize the expected whole-tree loss:

$$\hat{\mathbf{y}} = \operatorname*{argmax}_{\mathbf{y}} p_{\vec{\theta}}(\mathbf{y} \mid \mathbf{x}) = \operatorname*{argmin}_{\mathbf{y}} \mathbf{E}_{p_{\vec{\theta}}(\mathbf{Y}|\mathbf{x})}\left[-\delta(\mathbf{y}, \mathbf{Y})\right] \tag{14}$$

Minimum Bayes-risk decoding generalizes this idea to an arbitrary loss function ℓ on the proposed tree:

$$\hat{\mathbf{y}} = \operatorname*{argmin}_{\mathbf{y}} \mathbf{E}_{p_{\vec{\theta}}(\mathbf{Y}|\mathbf{x})}\left[\ell(\mathbf{y}, \mathbf{Y})\right] \tag{15}$$

This technique was originally applied in speech recognition (Goel and Byrne, 2000) and translation (Kumar and Byrne, 2004); Goodman (1996) proposed a similar idea in probabilistic context-free parsing, seeking to maximize expected recall. For more applications in parsing, see Petrov and Klein (2007).

The most common loss function used to evaluate dependency parsers is the number of attachment errors, so we seek to decode using:

$$\begin{aligned} \hat{\mathbf{y}} &= \operatorname*{argmin}_{\mathbf{y}} \mathbf{E}_{p_{\vec{\theta}}(\mathbf{Y}|\mathbf{x})}\left[\sum_{i=1}^{n} -\delta(\mathbf{y}(i), \mathbf{Y}(i))\right] \\ &= \operatorname*{argmax}_{\mathbf{y}} \sum_{i=1}^{n} p_{\vec{\theta}}(\mathbf{Y}(i) = \mathbf{y}(i) \mid \mathbf{x}) \end{aligned} \tag{16}$$

To apply this decoding method, we make use of Eq. 13, which gives us the posterior probabilities of edges under the model, and the same Chiu-Liu-Edmonds maximum directed spanning tree algorithm used for maximum *a posteriori* decoding. Note that this decoding method can be applied regardless of how the model is trained. It merely requires assuming that the tree scores under the trained model (probabilistic or not) can be treated as unnormalized log-probabilities over trees given the sentence $\mathbf{x}$.

We applied minimum Bayes-risk decoding to the models trained using MIRA and using conditional estimation (see Section 3.3). Table 1 shows that, across languages, minimum Bayes-risk decoding *hurts* slightly the performance of a MIRA-trained model, but *helps* slightly or does not affect the performance of a conditionally-trained model. Since MIRA does not attempt to model the distribution over trees, this result is not surprising; interpreting weights as defining a conditional log-linear distribution is questionable under MIRA's training criterion.

One option, which we do not test here, is to use minimum Bayes-risk decoding *inside* of MIRA training, to propose a hypothesis tree (or k-best trees) at each *training* step. Doing this would more closely match the training conditions with the testing conditions; however, it is unclear whether there is a formal interpretation of such a combination, for example its relationship to McDonald et al.'s "factored MIRA."

Minimum Bayes-risk decoding, we believe, will become important in nonprojective parsing with *non-edge-factored* models. Note that minimium Bayes-risk decoding reduces *any* parsing problem to the maximum directed spanning tree problem, even if the original model is not edge-factored. All that is required are the marginals $p_{\vec{\theta}}(\mathbf{Y}(i) = \mathbf{y}(i) \mid \mathbf{x})$, which may be intractable to compute exactly, though it may be possible to develop efficient approximations.

5 Hidden Variables

A third application of probability distributions over trees is hidden-variable learning. The Expectation-Maximization (EM) algorithm (Baum and Petrie, 1966; Dempster et al., 1977; Baker, 1979), for example, is a way to maximum the likelihood of training data, marginalizing out hidden variables. This has been applied widely in unsupervised parsing (Carroll and Charniak, 1992; Klein and Manning, 2002). More recently, EM has been used to learn hidden variables in parse trees; these can be head-child annotations (Chiang and Bikel, 2002), latent head features (Matsuzaki et al., 2005; Prescher, 2005; Dreyer and Eisner, 2006), or hierarchically-split nonterminal states (Petrov et al., 2006).

To date, we know of no attempts to apply hidden variables to supervised dependency tree models. If the trees are constrained to be projective, EM is easily applied using the inside-outside variant of the parsing algorithm described by Eisner (1996) to compute the marginal probability. Moving to the nonprojective case, there are two difficulties: (a) we must marginalize over nonprojective trees and (b) we must define a generative model over $(\mathbf{X}, \mathbf{Y})$.

We have already shown in Section 3 how to solve (a); here we avoid (b) by maximizing *conditional* likelihood, marginalizing out the hidden variable, denoted $\mathbf{z}$:

$$\max_{\vec{\theta}} \sum_{\mathbf{x},\mathbf{y}} \tilde{p}(\mathbf{x}, \mathbf{y}) \log \sum_{\mathbf{z}} p_{\vec{\theta}}(\mathbf{y}, \mathbf{z} \mid \mathbf{x}) \qquad (17)$$

This sort of conditional training with hidden variables was carried out by Koo and Collins (2005), for example, in reranking; it is related to the information bottleneck method (Tishby et al., 1999) and contrastive estimation (Smith and Eisner, 2005).

5.1 Latent Dependency Labels

Noting that our model is edge-factored (Eq. 2), we define our hidden variables to be edge-factored as well. We can think of the hidden variables as clusters on dependency tokens, and redefine the score of an edge to be:

$$s_{\mathbf{x},\vec{\theta}}(i, j) = \sum_{z \in \mathbb{Z}} e^{\vec{\theta} \cdot \vec{f}(\mathbf{x}, x_i, x_j, z)} \qquad (18)$$

where $\mathbb{Z}$ is a set of dependency clusters.

Note that keeping the model edge-factored means that the cluster of each dependency in a tree is conditionally independent of all the others, given the words. This is computationally advantageous (we can factor out the marginalization of the hidden variable by edge), and it permits the use of any clustering method at all. For example, if an auxiliary clustering model $q(\mathbf{z} \mid \mathbf{x}, \mathbf{y})$—perhaps one that did *not* make such independence assumptions—were used, the posterior probability $q(Z_i = z \mid \mathbf{x}, \mathbf{y})$ could be a feature in the proposed model. On the other hand, we must consider carefully the role of the dependency clusters in the model; if clusters are learned extrinsic to estimation of the parsing model, we should not expect them to be directly advantageous to parsing accuracy.

5.2 Experiments

We tried two sets of experiments with clustering. In one case, we simply augmented all of McDonald et al.'s edge features with a cluster label in hopes of improved accuracy. Models were initialized near zero, with Gaussian noise added to break symmetry among clusters.

Under these conditions, performance stayed the same or changed slightly (see Table 2); none of the improvements are significant. Note that three decoders were applied: maximum *a posteriori* (m*ap*) and minimum Bayes-risk (mBr) as described in Section 4, and "max-z," in which each possible edge was labeled and weighted only with its most likely cluster (rather than the sum over all clusters), before finding the most probable tree.[3] For each of the three languages tested, some number of clusters and some decoding method gave small improvements over the baseline.

More ambitiously, we hypothesized that many lexicalized features on edges could be "squeezed" through clusters to reduce the size of the feature set. We thus removed all word-word and lemma-lemma features and all tag fourgrams. Although this reduced our feature set by a factor of 60 or more (prior to taking a cross-product with the clusters), the damage of breaking the features was tremendous, and performance even with a thousand clusters barely broke 25% accuracy.

6 Discussion

Noting that adding latent features to nonterminals in unlexicalized context-free parsing has been very successful (Chiang and Bikel, 2002; Matsuzaki et al., 2005; Prescher, 2005; Dreyer and Eisner, 2006; Petrov et al., 2006), we were surprised not to see a more substantial performance improvement through latent features. We propose several interpretations. First, it may simply be that many more clusters may be required. Note that the label-set sizes for the labeled versions of these datasets are larger than 32 (e.g., 50 for Danish). This has the unfortunate effect of blowing up the feature space beyond the memory capacity of our machines (hence our attempts at squeezing high-dimensional features through the clusters).

# cl.	decoding	Arabic	Danish	Dutch
none	m*ap*=max-z	80.4	87.5	90.0
	mBr	80.5	87.5	90.0
2	m*ap*	80.4	87.5	89.5
	mBr	80.6	87.3	89.7
	max-z	80.4	86.3	89.4
16	m*ap*	80.4	87.6	90.1
	mBr	80.4	87.6	90.1
	max-z	80.4	87.6	90.2
32	m*ap*	80.0	87.6	–
	mBr	80.4	87.5	–
	max-z	80.0	87.5	–

Table 2: Augmenting edge features with clusters results in similar performance to conditional training with no clusters (top two lines). Scores are unlabeled dependency accuracy on test data.

Of course, improved clustering methods may also improve performance. In particular, a cluster-learning algorithm that permits clusters to split and/or merge, as in Petrov et al. (2006) or in Pereira et al. (1993), may be appropriate.

Given the relative simplicity of clustering methods for context-free parsing to date (gains were found just by using Expectation-Maximization), we believe the fundamental reason clustering was not particularly helpful here is a structural one. In context-free parsing, the latent features are (in published work to date) on nonterminal states, which are the stuctural "bridge" between context-free rules. Adding features to those states is a way of pushing information—encoded indirectly, perhaps—farther around the tree, and therefore circumventing the strict independence assumptions of probabilistic CFGs.

In an edge-factored dependency model, on the

[3] Czech experiments were not done, since the number of features (more than 14 million) was too high to multiply out by clusters.

other hand, latent features on the edges seem to have little effect. Given that they are locally "summed out" when we compute the scores of possible attachments, it should be clear that the edge clusters do not circumvent any independence assumptions. Three options appear to present themselves. First, we might attempt to learn clusters in tandem with estimating a richer, non-edge-factored model which would require approximations to $Z_{\vec{\theta}}(\mathbf{x})$, if conditional training were to be used. Note that the approximations to maximizing over spanning trees with second-order features, proposed by McDonald and Pereira (2006), do not permit estimating the clusters as part of the same process as weight estimation (at least not without modification). In the conditional estimation case, a variational approach might be appropriate. The second option is to learn clusters offline, *before* estimating the parser. (We suggested how to incorporate soft clusters into our model in Section 5.1.) This option is computationally advantageous but loses sight of the aim of learning the clusters specifically to improve parsing accuracy. Third, noting that the structural "bridge" between two coincident edges is the shared vertex (word), we might consider *word* token clustering.

We also believe this structural locality issue helps explain the modesty of the gains using minimum Bayes-risk decoding with conditional training (Section 4). In other dependency parsing scenarios, minimum Bayes-risk decoding has been found to offer significant advantages—why not here? Minimum Bayes-risk makes use of global statistical dependencies in the posterior when making local decisions. But in an edge-factored model, the edges are all conditionally independent, given that $\mathbf{y}$ is a spanning tree.

As a *post hoc* experiment, we compared purely greedy attachment (attach each word to its maximum-weighted parent, without any tree constraints). Edge scores as defined in the model were compared to minimum Bayes-risk posterior scores, and the latter were consistently better (though this always under-performed optimal spanning-tree decoding, unsurprisingly). This comparison serves only to confirm that minimum Bayes-risk decoding is a way to circumvent independence assumptions (here made by a decoder), but only when the trained model *does not* make those particular assumptions.

7 Conclusion

We have shown how to carry out exact marginalization under an edge-factored, conditional log-linear model over nonprojective dependency trees. The method has cubic runtime in the length of the sequence, but is very fast in practice. It can be used in conditional training of such a model, in minimum Bayes-risk decoding (regardless of how the model is trained), and in training with hidden variables. We demonstrated how each of these techniques gives results competitive with state-of-the-art existing dependency parsers.

Abstract

This paper provides an algorithmic framework for learning statistical models involving directed spanning trees, or equivalently non-projective dependency structures. We show how partition functions and marginals for directed spanning trees can be computed by an adaptation of Kirchhoff's Matrix-Tree Theorem. To demonstrate an application of the method, we perform experiments which use the algorithm in training both log-linear and max-margin dependency parsers. The new training methods give improvements in accuracy over perceptron-trained models.

1 Introduction

Learning with structured data typically involves searching or summing over a set with an exponential number of structured elements, for example the set of all parse trees for a given sentence. Methods for summing over such structures include the inside-outside algorithm for probabilistic context-free grammars (Baker, 1979), the forward-backward algorithm for hidden Markov models (Baum et al., 1970), and the belief-propagation algorithm for graphical models (Pearl, 1988). These algorithms compute marginal probabilities and partition functions, quantities which are central to many methods for the statistical modeling of complex structures (e.g., the EM algorithm (Baker, 1979; Baum et al., 1970), contrastive estimation (Smith and Eisner, 2005), training algorithms for CRFs (Lafferty et al., 2001), and training algorithms for max-margin models (Bartlett et al., 2004; Taskar et al., 2004a)).

This paper describes inside-outside-style algorithms for the case of directed spanning trees. These structures are equivalent to non-projective dependency parses (McDonald et al., 2005b), and more generally could be relevant to any task that involves learning a mapping from a graph to an underlying spanning tree. Unlike the case for projective dependency structures, partition functions and marginals for non-projective trees cannot be computed using dynamic-programming methods such as the inside-outside algorithm. In this paper we describe how these quantities can be computed by adapting a well-known result in graph theory: Kirchhoff's Matrix-Tree Theorem (Tutte, 1984). A naïve application of the theorem yields $O(n^4)$ and $O(n^6)$ algorithms for computation of the partition function and marginals, respectively. However, our adaptation finds the partition function and marginals in $O(n^3)$ time using simple matrix determinant and inversion operations.

We demonstrate an application of the new inference algorithm to non-projective dependency parsing. Specifically, we show how to implement two popular supervised learning approaches for this task: globally-normalized log-linear models and max-margin models. Log-linear estimation critically depends on the calculation of partition functions and marginals, which can be computed by our algorithms. For max-margin models, Bartlett et al. (2004) have provided a simple training algorithm, based on exponentiated-gradient (EG) updates, that requires computation of marginals and can thus be implemented within our framework. Both of these methods explicitly minimize the loss incurred when parsing the entire training set. This contrasts with the online learning algorithms used in previous work with spanning-tree models (McDonald et al., 2005b).

We applied the above two *marginal-based* training algorithms to six languages with varying degrees of non-projectivity, using datasets obtained from the CoNLL-X shared task (Buchholz and Marsi, 2006). Our experimental framework compared three training approaches: log-linear models, max-margin models, and the averaged perceptron. Each of these was applied to both projective and non-projective parsing. Our results demonstrate that marginal-based training yields models which out-

Proceedings of the 2007 Joint Conference on Empirical Methods in Natural Language Processing and Computational Natural Language Learning, pp. 141–150, Prague, June 2007. ©2007 Association for Computational Linguistics

perform those trained using the averaged perceptron.

In summary, the contributions of this paper are:

1. We introduce algorithms for *inside-outside-style* calculations for directed spanning trees, or equivalently non-projective dependency structures. These algorithms should have wide applicability in learning problems involving spanning-tree structures.

2. We illustrate the utility of these algorithms in log-linear training of dependency parsing models, and show improvements in accuracy when compared to averaged-perceptron training.

3. We also train max-margin models for dependency parsing via an EG algorithm (Bartlett et al., 2004). The experiments presented here constitute the first application of this algorithm to a large-scale problem. We again show improved performance over the perceptron.

The goal of our experiments is to give a rigorous comparative study of the marginal-based training algorithms and a highly-competitive baseline, the averaged perceptron, using the same feature sets for all approaches. We stress, however, that the purpose of this work is not to give competitive performance on the CoNLL data sets; this would require further engineering of the approach.

Similar adaptations of the Matrix-Tree Theorem have been developed independently and simultaneously by Smith and Smith (2007) and McDonald and Satta (2007); see Section 5 for more discussion.

2 Background

2.1 Discriminative Dependency Parsing

Dependency parsing is the task of mapping a sentence $\mathbf{x}$ to a dependency structure y. Given a sentence $\mathbf{x}$ with n words, a dependency for that sentence is a tuple (h, m) where $h \in [0 \ldots n]$ is the index of the head word in the sentence, and $m \in [1 \ldots n]$ is the index of a modifier word. The value $h = 0$ is a special *root-symbol* that may only appear as the head of a dependency. We use $\mathcal{D}(\mathbf{x})$ to refer to all possible dependencies for a sentence $\mathbf{x}$: $\mathcal{D}(\mathbf{x}) = \{(h, m) : h \in [0 \ldots n], m \in [1 \ldots n]\}$.

A dependency parse is a set of dependencies that forms a directed tree, with the sentence's root-symbol as its root. We will consider both *projective* trees, where dependencies are not allowed to cross, and *non-projective* trees, where crossing dependencies are allowed. Dependency annotations for some languages, for example Czech, can exhibit a significant number of crossing dependencies. In addition, we consider both *single-root* and *multi-root* trees. In a single-root tree y, the root-symbol has exactly one child, while in a multi-root tree, the root-symbol has one or more children. This distinction is relevant as our training sets include both single-root corpora (in which all trees are single-root structures) and multi-root corpora (in which some trees are multi-root structures).

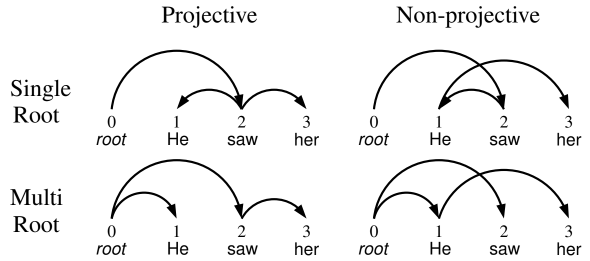

Figure 1: Examples of the four types of dependency structures. We draw dependency arcs from head to modifier.

The two distinctions described above are orthogonal, yielding four classes of dependency structures; see Figure 1 for examples of each kind of structure. We use $\mathcal{T}_p^s(\mathbf{x})$ to denote the set of all possible projective single-root dependency structures for a sentence $\mathbf{x}$, and $\mathcal{T}_{np}^s(\mathbf{x})$ to denote the set of single-root non-projective structures for $\mathbf{x}$. The sets $\mathcal{T}_p^m(\mathbf{x})$ and $\mathcal{T}_{np}^m(\mathbf{x})$ are defined analogously for multi-root structures. In contexts where any class of dependency structures may be used, we use the notation $\mathcal{T}(\mathbf{x})$ as a placeholder that may be defined as $\mathcal{T}_p^s(\mathbf{x})$, $\mathcal{T}_{np}^s(\mathbf{x})$, $\mathcal{T}_p^m(\mathbf{x})$ or $\mathcal{T}_{np}^m(\mathbf{x})$.

Following McDonald et al. (2005a), we use a discriminative model for dependency parsing. Features in the model are defined through a function $\mathbf{f}(\mathbf{x}, h, m)$ which maps a sentence $\mathbf{x}$ together with a dependency (h, m) to a feature vector in $\mathbb{R}^d$. A feature vector can be sensitive to any properties of the triple $(\mathbf{x}, h, m)$. Given a parameter vector $\mathbf{w}$, the optimal dependency structure for a sentence $\mathbf{x}$ is

$$y^*(\mathbf{x}; \mathbf{w}) = \operatorname*{argmax}_{y \in \mathcal{T}(\mathbf{x})} \sum_{(h,m) \in y} \mathbf{w} \cdot \mathbf{f}(\mathbf{x}, h, m) \quad (1)$$

where the set $\mathcal{T}(\mathbf{x})$ can be defined as $\mathcal{T}_p^s(\mathbf{x})$, $\mathcal{T}_{np}^s(\mathbf{x})$, $\mathcal{T}_p^m(\mathbf{x})$ or $\mathcal{T}_{np}^m(\mathbf{x})$, depending on the type of parsing.

The parameters $\mathbf{w}$ will be learned from a training set $\{(\mathbf{x}_i, y_i)\}_{i=1}^N$ where each $\mathbf{x}_i$ is a sentence and each y_i is a dependency structure. Much of the previous work on learning $\mathbf{w}$ has focused on training local models (see Section 5). McDonald et al. (2005a; 2005b) trained global models using online algorithms such as the perceptron algorithm or MIRA. In this paper we consider training algorithms based on work in conditional random fields (CRFs) (Lafferty et al., 2001) and max-margin methods (Taskar et al., 2004a).

2.2 Three Inference Problems

This section highlights three inference problems which arise in training and decoding discriminative dependency parsers, and which are central to the approaches described in this paper.

Assume that we have a vector $\boldsymbol{\theta}$ with values $\theta_{h,m} \in \mathbb{R}$ for all $(h, m) \in \mathcal{D}(\mathbf{x})$; these values correspond to weights on the different dependencies in $\mathcal{D}(\mathbf{x})$. Define a conditional distribution over all dependency structures $y \in \mathcal{T}(\mathbf{x})$ as follows:

$$P(y \,|\, \mathbf{x}; \boldsymbol{\theta}) = \frac{\exp\left\{\sum_{(h,m)\in y} \theta_{h,m}\right\}}{Z(\mathbf{x}; \boldsymbol{\theta})} \quad (2)$$

$$Z(\mathbf{x}; \boldsymbol{\theta}) = \sum_{y\in\mathcal{T}(\mathbf{x})} \exp\left\{\sum_{(h,m)\in y} \theta_{h,m}\right\} \quad (3)$$

The function $Z(\mathbf{x}; \boldsymbol{\theta})$ is commonly referred to as the *partition function*.

Given the distribution $P(y \,|\, \mathbf{x}; \boldsymbol{\theta})$, we can define the *marginal probability* of a dependency (h, m) as

$$\mu_{h,m}(\mathbf{x}; \boldsymbol{\theta}) = \sum_{y\in\mathcal{T}(\mathbf{x})\,:\,(h,m)\in y} P(y \,|\, \mathbf{x}; \boldsymbol{\theta})$$

The inference problems are then as follows:

Problem 1: **Decoding:**
Find $\mathrm{argmax}_{y\in\mathcal{T}(\mathbf{x})} \sum_{(h,m)\in y} \theta_{h,m}$

Problem 2: **Computation of the Partition Function:** Calculate $Z(\mathbf{x}; \boldsymbol{\theta})$.

Problem 3: **Computation of the Marginals:**
For all $(h, m) \in \mathcal{D}(\mathbf{x})$, calculate $\mu_{h,m}(\mathbf{x}; \boldsymbol{\theta})$.

Note that all three problems require a maximization or summation over the set $\mathcal{T}(\mathbf{x})$, which is exponential in size. There is a clear motivation for being able to solve Problem 1: by setting $\theta_{h,m} = \mathbf{w} \cdot \mathbf{f}(\mathbf{x}, h, m)$, the optimal dependency structure $y^*(\mathbf{x}; \mathbf{w})$ (see Eq. 1) can be computed. In this paper the motivation for solving Problems 2 and 3 arises from training algorithms for discriminative models. As we will describe in Section 4, both log-linear and max-margin models can be trained via methods that make direct use of algorithms for Problems 2 and 3.

In the case of projective dependency structures (i.e., $\mathcal{T}(\mathbf{x})$ defined as $\mathcal{T}_p^s(\mathbf{x})$ or $\mathcal{T}_p^m(\mathbf{x})$), there are well-known algorithms for all three inference problems. Decoding can be carried out using Viterbi-style dynamic-programming algorithms, for example the $O(n^3)$ algorithm of Eisner (1996). Computation of the marginals and partition function can also be achieved in $O(n^3)$ time, using a variant of the inside-outside algorithm (Baker, 1979) applied to the Eisner (1996) data structures (Paskin, 2001).

In the non-projective case (i.e., $\mathcal{T}(\mathbf{x})$ defined as $\mathcal{T}_{np}^s(\mathbf{x})$ or $\mathcal{T}_{np}^m(\mathbf{x})$), McDonald et al. (2005b) describe how the CLE algorithm (Chu and Liu, 1965; Edmonds, 1967) can be used for decoding. However, it is not possible to compute the marginals and partition function using the inside-outside algorithm. We next describe a method for computing these quantities in $O(n^3)$ time using matrix inverse and determinant operations.

3 Spanning-tree inference using the Matrix-Tree Theorem

In this section we present algorithms for computing the partition function and marginals, as defined in Section 2.2, for non-projective parsing. We first reiterate the observation of McDonald et al. (2005a) that non-projective parses correspond to directed spanning trees on a complete directed graph of n nodes, where n is the length of the sentence. The above inference problems thus involve summation over the set of all directed spanning trees. Note that this set is exponentially large, and there is no obvious method for decomposing the sum into dynamic-programming-like subproblems. This section describes how a variant of Kirchhoff's Matrix-Tree Theorem (Tutte, 1984) can be used to evaluate the partition function and marginals efficiently.

In what follows, we consider the single-root setting (i.e., $\mathcal{T}(\mathbf{x}) = \mathcal{T}_{np}^s(\mathbf{x})$), leaving the multi-root case (i.e., $\mathcal{T}(\mathbf{x}) = \mathcal{T}^m_{np}(\mathbf{x})$) to Section 3.3. For a sentence $\mathbf{x}$ with n words, define a complete directed graph G on n nodes, where each node corresponds to a word in $\mathbf{x}$, and each edge corresponds to a dependency between two words in $\mathbf{x}$. Note that G does *not* include the root-symbol $h = 0$, nor does it account for any dependencies $(0, m)$ headed by the root-symbol. We assign non-negative weights to the edges of this graph, yielding the following weighted adjacency matrix $A(\boldsymbol{\theta}) \in \mathbb{R}^{n \times n}$, for $h, m = 1 \ldots n$:

$$A_{h,m}(\boldsymbol{\theta}) \;=\; \begin{cases} 0, & \text{if } h = m \\ \exp\{\theta_{h,m}\}, & \text{otherwise} \end{cases}$$

To account for the dependencies $(0, m)$ headed by the root-symbol, we define a vector of root-selection scores $\mathbf{r}(\boldsymbol{\theta}) \in \mathbb{R}^n$, for $m = 1 \ldots n$:

$$r_m(\boldsymbol{\theta}) \;=\; \exp\{\theta_{0,m}\}$$

Let the weight of a dependency structure $y \in \mathcal{T}^s_{np}(\mathbf{x})$ be defined as:

$$\psi(y; \boldsymbol{\theta}) \;=\; r_{\text{root}(y)}(\boldsymbol{\theta}) \prod_{(h,m) \in y \,:\, h \neq 0} A_{h,m}(\boldsymbol{\theta})$$

Here, $\text{root}(y) = m : (0, m) \in y$ is the child of the root-symbol; there is exactly one such child, since $y \in \mathcal{T}^s_{np}(\mathbf{x})$. Eq. 2 and 3 can be rephrased as:

$$P(y \,|\, \mathbf{x}; \boldsymbol{\theta}) \;=\; \frac{\psi(y; \boldsymbol{\theta})}{Z(\mathbf{x}; \boldsymbol{\theta})} \qquad (4)$$

$$Z(\mathbf{x}; \boldsymbol{\theta}) \;=\; \sum_{y \in \mathcal{T}^s_{np}(\mathbf{x})} \psi(y; \boldsymbol{\theta}) \qquad (5)$$

In the remainder of this section, we drop the notational dependence on $\mathbf{x}$ for brevity.

The original Matrix-Tree Theorem addressed the problem of counting the number of undirected spanning trees in an undirected graph. For the models we study here, we require a sum of *weighted* and *directed* spanning trees. Tutte (1984) extended the Matrix-Tree Theorem to this case. We briefly summarize his method below.

First, define the Laplacian matrix $L(\boldsymbol{\theta}) \in \mathbb{R}^{n \times n}$ of G, for $h, m = 1 \ldots n$:

$$L_{h,m}(\boldsymbol{\theta}) \;=\; \begin{cases} \sum_{h'=1}^{n} A_{h',m}(\boldsymbol{\theta}) & \text{if } h = m \\ -A_{h,m}(\boldsymbol{\theta}) & \text{otherwise} \end{cases}$$

Second, for a matrix X, let $X^{(h,m)}$ be the *minor* of X with respect to row h and column m; i.e., the determinant of the matrix formed by deleting row h and column m from X. Finally, define the weight of any directed spanning tree of G to be the product of the weights $A_{h,m}(\boldsymbol{\theta})$ for the edges in that tree.

Theorem 1 *(Tutte, 1984, p. 140). Let $L(\boldsymbol{\theta})$ be the Laplacian matrix of G. Then $L^{(m,m)}(\boldsymbol{\theta})$ is equal to the sum of the weights of all directed spanning trees of G which are rooted at m. Furthermore, the minors vary only in sign when traversing the columns of the Laplacian (Tutte, 1984, p. 150):*

$$\forall h, m\colon\; (-1)^{h+m} L^{(h,m)}(\boldsymbol{\theta}) \;=\; L^{(m,m)}(\boldsymbol{\theta}) \qquad (6)$$

3.1 Partition functions via matrix determinants

From Theorem 1, it directly follows that

$$L^{(m,m)}(\boldsymbol{\theta}) \;=\; \sum_{y \in \mathcal{U}(m)} \;\prod_{(h,m) \in y \,:\, h \neq 0} A_{h,m}(\boldsymbol{\theta})$$

where $\mathcal{U}(m) = \{y \in \mathcal{T}^s_{np} : \text{root}(y) = m\}$. A naïve method for computing the partition function is therefore to evaluate

$$Z(\boldsymbol{\theta}) \;=\; \sum_{m=1}^{n} r_m(\boldsymbol{\theta}) L^{(m,m)}(\boldsymbol{\theta})$$

The above would require calculating n determinants, resulting in $O(n^4)$ complexity. However, as we show below $Z(\boldsymbol{\theta})$ may be obtained in $O(n^3)$ time using a single determinant evaluation.

Define a new matrix $\hat{L}(\boldsymbol{\theta})$ to be $L(\boldsymbol{\theta})$ with the first row replaced by the root-selection scores:

$$\hat{L}_{h,m}(\boldsymbol{\theta}) \;=\; \begin{cases} r_m(\boldsymbol{\theta}) & h = 1 \\ L_{h,m}(\boldsymbol{\theta}) & h > 1 \end{cases}$$

This matrix allows direct computation of the partition function, as the following proposition shows.

Proposition 1 *The partition function in Eq. 5 is given by $Z(\boldsymbol{\theta}) = |\hat{L}(\boldsymbol{\theta})|$.*

Proof: *Consider the row expansion of $|\hat{L}(\boldsymbol{\theta})|$ with respect to row 1:*

$$\begin{aligned} |\hat{L}(\boldsymbol{\theta})| &= \sum_{m=1}^{n} (-1)^{1+m} \hat{L}_{1,m}(\boldsymbol{\theta}) \hat{L}^{(1,m)}(\boldsymbol{\theta}) \\ &= \sum_{m=1}^{n} (-1)^{1+m} r_m(\boldsymbol{\theta}) L^{(1,m)}(\boldsymbol{\theta}) \\ &= \sum_{m=1}^{n} r_m(\boldsymbol{\theta}) L^{(m,m)}(\boldsymbol{\theta}) \;=\; Z(\boldsymbol{\theta}) \end{aligned}$$

The second line follows from the construction of $\hat{L}(\boldsymbol{\theta})$, and the third line follows from Eq. 6. ■

3.2 Marginals via matrix inversion

The marginals we require are given by

$$\mu_{h,m}(\boldsymbol{\theta}) \;=\; \frac{1}{Z(\boldsymbol{\theta})} \sum_{y \in \mathcal{T}^s_{np} :\, (h,m) \in y} \psi(y; \boldsymbol{\theta})$$

To calculate these marginals efficiently for all values of (h, m) we use a well-known identity relating the log partition-function to marginals

$$\mu_{h,m}(\boldsymbol{\theta}) \;=\; \frac{\partial \log Z(\boldsymbol{\theta})}{\partial \theta_{h,m}}$$

Since the partition function in this case has a closed-form expression (i.e., the determinant of a matrix constructed from $\boldsymbol{\theta}$), the marginals can also obtained in closed form. Using the chain rule, the derivative of the log partition-function in Proposition 1 is

$$\begin{aligned} \mu_{h,m}(\boldsymbol{\theta}) &= \frac{\partial \log |\hat{L}(\boldsymbol{\theta})|}{\partial \theta_{h,m}} \\ &= \sum_{h'=1}^{n} \sum_{m'=1}^{n} \frac{\partial \log |\hat{L}(\boldsymbol{\theta})|}{\partial \hat{L}_{h',m'}(\boldsymbol{\theta})} \frac{\partial \hat{L}_{h',m'}(\boldsymbol{\theta})}{\partial \theta_{h,m}} \end{aligned}$$

To perform the derivative, we use the identity

$$\frac{\partial \log |X|}{\partial X} \;=\; \left(X^{-1}\right)^T$$

and the fact that $\partial \hat{L}_{h',m'}(\boldsymbol{\theta}) / \partial \theta_{h,m}$ is nonzero for only a few h', m'. Specifically, when $h = 0$, the marginals are given by

$$\mu_{0,m}(\boldsymbol{\theta}) \;=\; r_m(\boldsymbol{\theta}) \left[\hat{L}^{-1}(\boldsymbol{\theta})\right]_{m,1}$$

and for $h > 0$, the marginals are given by

$$\begin{aligned} \mu_{h,m}(\boldsymbol{\theta}) \;=\; & (1 - \delta_{1,m}) A_{h,m}(\boldsymbol{\theta}) \left[\hat{L}^{-1}(\boldsymbol{\theta})\right]_{m,m} - \\ & (1 - \delta_{h,1}) A_{h,m}(\boldsymbol{\theta}) \left[\hat{L}^{-1}(\boldsymbol{\theta})\right]_{m,h} \end{aligned}$$

where $\delta_{h,m}$ is the Kronecker delta. Thus, the complexity of evaluating *all* the relevant marginals is dominated by the matrix inversion, and the total complexity is therefore $O(n^3)$.

3.3 Multiple Roots

In the case of multiple roots, we can still compute the partition function and marginals efficiently. In fact, the derivation of this case is simpler than for single-root structures. Create an extended graph G' which augments G with a dummy root node that has edges pointing to all of the existing nodes, weighted by the appropriate root-selection scores. Note that there is a bijection between directed spanning trees of G' rooted at the dummy root and multi-root structures $y \in \mathcal{T}^m_{np}(\mathbf{x})$. Thus, Theorem 1 can be used to compute the partition function directly: construct a Laplacian matrix $L(\boldsymbol{\theta})$ for G' and compute the minor $L^{(0,0)}(\boldsymbol{\theta})$. Since this minor is also a determinant, the marginals can be obtained analogously to the single-root case. More concretely, this technique corresponds to defining the matrix $\hat{L}(\boldsymbol{\theta})$ as

$$\hat{L}(\boldsymbol{\theta}) \;=\; L(\boldsymbol{\theta}) + \mathrm{diag}(\mathbf{r}(\boldsymbol{\theta}))$$

where $\mathrm{diag}(\mathbf{v})$ is the diagonal matrix with the vector $\mathbf{v}$ on its diagonal.

3.4 Labeled Trees

The techniques above extend easily to the case where dependencies are labeled. For a model with L different labels, it suffices to define the edge and root scores as $A_{h,m}(\boldsymbol{\theta}) = \sum_{\ell=1}^{L} \exp\{\theta_{h,m,\ell}\}$ and $r_m(\boldsymbol{\theta}) = \sum_{\ell=1}^{L} \exp\{\theta_{0,m,\ell}\}$. The partition function over labeled trees is obtained by operating on these values as described previously, and the marginals are given by an application of the chain rule. Both inference problems are solvable in $O(n^3 + Ln^2)$ time.

4 Training Algorithms

This section describes two methods for parameter estimation that rely explicitly on the computation of the partition function and marginals.

4.1 Log-Linear Estimation

In conditional log-linear models (Johnson et al., 1999; Lafferty et al., 2001), a distribution over parse trees for a sentence $\mathbf{x}$ is defined as follows:

$$P(y \,|\, \mathbf{x}; \mathbf{w}) \;=\; \frac{\exp\left\{\sum_{(h,m) \in y} \mathbf{w} \cdot \mathbf{f}(\mathbf{x}, h, m)\right\}}{Z(\mathbf{x}; \mathbf{w})} \qquad (7)$$

where $Z(\mathbf{x}; \mathbf{w})$ is the partition function, a sum over $\mathcal{T}^s_p(\mathbf{x})$, $\mathcal{T}^s_{np}(\mathbf{x})$, $\mathcal{T}^m_p(\mathbf{x})$ or $\mathcal{T}^m_{np}(\mathbf{x})$.

We train the model using the approach described by Sha and Pereira (2003). Assume that we have a training set $\{(\mathbf{x}_i, y_i)\}_{i=1}^N$. The optimal parameters are taken to be $\mathbf{w}^* = \mathrm{argmin}_{\mathbf{w}} L(\mathbf{w})$ where

$$L(\mathbf{w}) \;=\; -C\sum_{i=1}^{N} \log P(y_i \,|\, \mathbf{x}_i; \mathbf{w}) + \frac{1}{2}||\mathbf{w}||^2$$

The parameter $C > 0$ is a constant dictating the level of regularization in the model.

Since $L(\mathbf{w})$ is a convex function, gradient descent methods can be used to search for the global minimum. Such methods typically involve repeated computation of the loss $L(\mathbf{w})$ and gradient $\frac{\partial L(\mathbf{w})}{\partial \mathbf{w}}$, requiring efficient implementations of both functions. Note that the log-probability of a parse is

$$\log P(y \,|\, \mathbf{x}; \mathbf{w}) = \sum_{(h,m)\in y} \mathbf{w}\cdot\mathbf{f}(\mathbf{x}, h, m) - \log Z(\mathbf{x}; \mathbf{w})$$

so that the main issue in calculating the loss function $L(\mathbf{w})$ is the evaluation of the partition functions $Z(\mathbf{x}_i; \mathbf{w})$. The gradient of the loss is given by

$$\begin{aligned}\frac{\partial L(\mathbf{w})}{\partial \mathbf{w}} \;&=\; \mathbf{w} - C\sum_{i=1}^{N} \sum_{(h,m)\in y_i} \mathbf{f}(\mathbf{x}_i, h, m) \\ &+ C\sum_{i=1}^{N} \sum_{(h,m)\in \mathcal{D}(\mathbf{x}_i)} \mu_{h,m}(\mathbf{x}_i; \mathbf{w})\mathbf{f}(\mathbf{x}_i, h, m)\end{aligned}$$

where

$$\mu_{h,m}(\mathbf{x}; \mathbf{w}) \;=\; \sum_{y\in\mathcal{T}(\mathbf{x})\,:\,(h,m)\in y} P(y \,|\, \mathbf{x}; \mathbf{w})$$

is the marginal probability of a dependency (h, m). Thus, the main issue in the evaluation of the gradient is the computation of the marginals $\mu_{h,m}(\mathbf{x}_i; \mathbf{w})$.

Note that Eq. 7 forms a special case of the log-linear distribution defined in Eq. 2 in Section 2.2. If we set $\theta_{h,m} = \mathbf{w}\cdot\mathbf{f}(\mathbf{x}, h, m)$ then we have $P(y \,|\, \mathbf{x}; \mathbf{w}) = P(y \,|\, \mathbf{x}; \boldsymbol{\theta})$, $Z(\mathbf{x}; \mathbf{w}) = Z(\mathbf{x}; \boldsymbol{\theta})$, and $\mu_{h,m}(\mathbf{x}; \mathbf{w}) = \mu_{h,m}(\mathbf{x}; \boldsymbol{\theta})$. Thus in the projective case the inside-outside algorithm can be used to calculate the partition function and marginals, thereby enabling training of a log-linear model; in the non-projective case the algorithms in Section 3 can be used for this purpose.

4.2 Max-Margin Estimation

The second learning algorithm we consider is the large-margin approach for structured prediction (Taskar et al., 2004a; Taskar et al., 2004b). Learning in this framework again involves minimization of a convex function $L(\mathbf{w})$. Let the *margin* for parse tree y on the i'th training example be defined as

$$m_{i,y}(\mathbf{w}) = \sum_{(h,m)\in y_i} \mathbf{w}\cdot\mathbf{f}(\mathbf{x}_i, h, m) - \sum_{(h,m)\in y} \mathbf{w}\cdot\mathbf{f}(\mathbf{x}_i, h, m)$$

The loss function is then defined as

$$L(\mathbf{w}) = C\sum_{i=1}^{N} \max_{y\in\mathcal{T}(\mathbf{x}_i)} \left(E_{i,y} - m_{i,y}(\mathbf{w})\right) + \frac{1}{2}||\mathbf{w}||^2$$

where $E_{i,y}$ is a measure of the loss—or number of errors—for parse y on the i'th training sentence. In this paper we take $E_{i,y}$ to be the number of incorrect dependencies in the parse tree y when compared to the gold-standard parse tree y_i.

The definition of $L(\mathbf{w})$ makes use of the expression $\max_{y\in\mathcal{T}(\mathbf{x}_i)} (E_{i,y} - m_{i,y}(\mathbf{w}))$ for the i'th training example, which is commonly referred to as the *hinge loss*. Note that $E_{i,y_i} = 0$, and also that $m_{i,y_i}(\mathbf{w}) = 0$, so that the hinge loss is always non-negative. In addition, the hinge loss is 0 if and only if $m_{i,y}(\mathbf{w}) \geq E_{i,y}$ for all $y \in \mathcal{T}(\mathbf{x}_i)$. Thus the hinge loss directly penalizes margins $m_{i,y}(\mathbf{w})$ which are less than their corresponding losses $E_{i,y}$.

Figure 2 shows an algorithm for minimizing $L(\mathbf{w})$ that is based on the exponentiated-gradient algorithm for large-margin optimization described by Bartlett et al. (2004). The algorithm maintains a set of weights $\theta_{i,h,m}$ for $i = 1 \ldots N, (h, m) \in \mathcal{D}(\mathbf{x}_i)$, which are updated example-by-example. The algorithm relies on the repeated computation of marginal values $\mu_{i,h,m}$, which are defined as follows:[1]

$$\begin{aligned}\mu_{i,h,m} \;&=\; \sum_{y\in\mathcal{T}(\mathbf{x}_i)\,:\,(h,m)\in y} P(y \,|\, \mathbf{x}_i) \qquad (8) \\ P(y \,|\, \mathbf{x}_i) \;&=\; \frac{\exp\left\{\sum_{(h,m)\in y} \theta_{i,h,m}\right\}}{\sum_{y'\in\mathcal{T}(\mathbf{x}_i)} \exp\left\{\sum_{(h,m)\in y'} \theta_{i,h,m}\right\}}\end{aligned}$$

A similar definition is used to derive marginal values $\mu'_{i,h,m}$ from the values $\theta'_{i,h,m}$. Computation of the μ and μ' values is again inference of the form described in Problem 3 in Section 2.2, and can be

[1] Bartlett et al. (2004) write $P(y \,|\, \mathbf{x}_i)$ as $\alpha_{i,y}$. The $\alpha_{i,y}$ variables are dual variables that appear in the dual objective function, i.e., the convex dual of $L(\mathbf{w})$. Analysis of the algorithm shows that as the $\theta_{i,h,m}$ variables are updated, the dual variables converge to the optimal point of the dual objective, and the parameters $\mathbf{w}$ converge to the minimum of $L(\mathbf{w})$.

Inputs: Training examples $\{(\mathbf{x}_i, y_i)\}_{i=1}^{N}$.

Parameters: Regularization constant C, starting point β, number of passes over training set T.

Data Structures: Real values $\theta_{i,h,m}$ and $l_{i,h,m}$ for $i = 1 \ldots N, (h,m) \in \mathcal{D}(\mathbf{x}_i)$. Learning rate η.

Initialization: Set learning rate $\eta = \frac{1}{C}$. Set $\theta_{i,h,m} = \beta$ for $(h,m) \in y_i$, and $\theta_{i,h,m} = 0$ for $(h,m) \notin y_i$. Set $l_{i,h,m} = 0$ for $(h,m) \in y_i$, and $l_{i,h,m} = 1$ for $(h,m) \notin y_i$. Calculate initial parameters as

$$\mathbf{w} = C \sum_i \sum_{(h,m) \in \mathcal{D}(\mathbf{x}_i)} \delta_{i,h,m} \mathbf{f}(\mathbf{x}_i, h, m)$$

where $\delta_{i,h,m} = (1 - l_{i,h,m} - \mu_{i,h,m})$ and the $\mu_{i,h,m}$ values are calculated from the $\theta_{i,h,m}$ values as described in Eq. 8.

Algorithm: Repeat T passes over the training set, where each pass is as follows:

```
Set $obj = 0$

For $i = 1 \ldots N$
  • For all $(h,m) \in \mathcal{D}(\mathbf{x}_i)$:
    $\theta'_{i,h,m} = \theta_{i,h,m} + \eta C \left( l_{i,h,m} + \mathbf{w} \cdot \mathbf{f}(\mathbf{x}_i, h, m) \right)$

    • For example $i$, calculate marginals $\mu_{i,h,m}$
    from $\theta_{i,h,m}$ values, and marginals $\mu'_{i,h,m}$
    from $\theta'_{i,h,m}$ values (see Eq. 8).

  • Update the parameters:
    $\mathbf{w} = \mathbf{w} + C \sum_{(h,m) \in \mathcal{D}(\mathbf{x}_i)} \delta_{i,h,m} \mathbf{f}(\mathbf{x}_i, h, m)$
    where $\delta_{i,h,m} = \mu_{i,h,m} - \mu'_{i,h,m}$,

  • For all $(h,m) \in \mathcal{D}(\mathbf{x}_i)$, set $\theta_{i,h,m} = \theta'_{i,h,m}$

  • Set $obj = obj + C \sum_{(h,m) \in \mathcal{D}(\mathbf{x}_i)} l_{i,h,m} \mu'_{i,h,m}$

Set $obj = obj - \frac{||\mathbf{w}||^2}{2}$. If $obj$ has decreased
compared to last iteration, set $\eta = \frac{\eta}{2}$.
```

Output: Parameter values $\mathbf{w}$.

Figure 2: The EG Algorithm for Max-Margin Estimation. The learning rate η is halved each time the dual objective function (see (Bartlett et al., 2004)) fails to increase. In our experiments we chose $\beta = 9$, which was found to work well during development of the algorithm.

achieved using the inside-outside algorithm for projective structures, and the algorithms described in Section 3 for non-projective structures.

5 Related Work

Global log-linear training has been used in the context of PCFG parsing (Johnson, 2001). Riezler et al. (2004) explore a similar application of log-linear models to LFG parsing. Max-margin learning has been applied to PCFG parsing by Taskar et al. (2004b). They show that this problem has a QP dual of polynomial size, where the dual variables correspond to marginal probabilities of CFG rules. A similar QP dual may be obtained for max-margin projective dependency parsing. However, for non-projective parsing, the dual QP would require an exponential number of constraints on the dependency marginals (Chopra, 1989). Nevertheless, alternative optimization methods like that of Tsochantaridis et al. (2004), or the EG method presented here, can still be applied.

The majority of previous work on dependency parsing has focused on local (i.e., classification of individual edges) discriminative training methods (Yamada and Matsumoto, 2003; Nivre et al., 2004; Y. Cheng, 2005). Non-local (i.e., classification of entire trees) training methods were used by McDonald et al. (2005a), who employed online learning.

Dependency parsing accuracy can be improved by allowing second-order features, which consider more than one dependency simultaneously. McDonald and Pereira (2006) define a second-order dependency parsing model in which interactions between adjacent siblings are allowed, and Carreras (2007) defines a second-order model that allows grandparent and sibling interactions. Both authors give polytime algorithms for exact projective parsing. By adapting the inside-outside algorithm to these models, partition functions and marginals can be computed for second-order projective structures, allowing log-linear and max-margin training to be applied via the framework developed in this paper. For higher-order non-projective parsing, however, computational complexity results (McDonald and Pereira, 2006; McDonald and Satta, 2007) indicate that exact solutions to the three inference problems of Section 2.2 will be intractable. Exploration of approximate second-order non-projective inference is a natural avenue for future research.

Two other groups of authors have independently and simultaneously proposed adaptations of the Matrix-Tree Theorem for structured inference on directed spanning trees (McDonald and Satta, 2007; Smith and Smith, 2007). There are some algorithmic differences between these papers and ours. First, we define both multi-root and single-root algorithms, whereas the other papers only consider multi-root parsing. This distinction can be important as one often expects a dependency structure to have exactly one child attached to the root-symbol, as is the case in a single-root structure. Second, McDonald and Satta (2007) propose an $O(n^5)$ algorithm for computing the marginals, as opposed to the $O(n^3)$ matrix-inversion approach used by Smith and Smith (2007) and ourselves.

In addition to the algorithmic differences, both groups of authors consider applications of the Matrix-Tree Theorem which we have not discussed. For example, both papers propose minimum-risk decoding, and McDonald and Satta (2007) discuss unsupervised learning and language modeling, while Smith and Smith (2007) define hidden-variable models based on spanning trees.

In this paper we used EG training methods only for max-margin models (Bartlett et al., 2004). However, Globerson et al. (2007) have recently shown how EG updates can be applied to efficient training of log-linear models.

6 Experiments on Dependency Parsing

In this section, we present experimental results applying our inference algorithms for dependency parsing models. Our primary purpose is to establish comparisons along two relevant dimensions: projective training vs. non-projective training, and marginal-based training algorithms vs. the averaged perceptron. The feature representation and other relevant dimensions are kept fixed in the experiments.

6.1 Data Sets and Features

We used data from the CoNLL-X shared task on multilingual dependency parsing (Buchholz and Marsi, 2006). In our experiments, we used a subset consisting of six languages; Table 1 gives details of the data sets used.[2] For each language we created a validation set that was a subset of the CoNLL-X training set for that language. The remainder of each training set was used to train the models for the different languages. The validation sets were used to tune the meta-parameters (e.g., the value of the regularization constant C) of the different training algorithms. We used the official test sets and evaluation script from the CoNLL-X task. All of the results that we report are for unlabeled dependency parsing.[3]

language	%cd	train	val.	test
Arabic	0.34	49,064	5,315	5,373
Dutch	4.93	178,861	16,208	5,585
Japanese	0.70	141,966	9,495	5,711
Slovene	1.59	22,949	5,801	6,390
Spanish	0.06	78,310	11,024	5,694
Turkish	1.26	51,827	5,683	7,547

Table 1: Information for the languages in our experiments. The 2nd column (%cd) is the percentage of crossing dependencies in the training and validation sets. The last three columns report the size in tokens of the training, validation and test sets.

The non-projective models were trained on the CoNLL-X data in its original form. Since the projective models assume that the dependencies in the data are non-crossing, we created a second training set for each language where non-projective dependency structures were automatically transformed into projective structures. All projective models were trained on these new training sets.[4] Our feature space is based on that of McDonald et al. (2005a).[5]

6.2 Results

We performed experiments using three training algorithms: the averaged perceptron (Collins, 2002), log-linear training (via conjugate gradient descent), and max-margin training (via the EG algorithm). Each of these algorithms was trained using projective and non-projective methods, yielding six training settings per language. The different training algorithms have various meta-parameters, which we optimized on the validation set for each language/training-setting combination. The

[2] Our subset includes the two languages with the lowest accuracy in the CoNLL-X evaluations (Turkish and Arabic), the language with the highest accuracy (Japanese), the most non-projective language (Dutch), a moderately non-projective language (Slovene), and a highly projective language (Spanish). All languages but Spanish have multi-root parses in their data. We are grateful to the providers of the treebanks that constituted the data of our experiments (Hajič et al., 2004; van der Beek et al., 2002; Kawata and Bartels, 2000; Džeroski et al., 2006; Civit and Martí, 2002; Oflazer et al., 2003).

[3] Our algorithms also support labeled parsing (see Section 3.4). Initial experiments with labeled models showed the same trend that we report here for unlabeled parsing, so for simplicity we conducted extensive experiments only for unlabeled parsing.

[4] The transformations were performed by running the projective parser with score +1 on correct dependencies and -1 otherwise: the resulting trees are guaranteed to be projective and to have a minimum loss with respect to the correct tree. Note that only the training sets were transformed.

[5] It should be noted that McDonald et al. (2006) use a richer feature set that is incomparable to our features.

	Perceptron		Max-Margin		Log-Linear	
	p	np	p	np	p	np
Ara	71.74	71.84	71.74	72.99	73.11	**73.67**

Tur	71.22	71.70	**72.83**	72.02	72.26	72.62

Table 2: Test data results. The p and np columns show results with projective and non-projective training respectively.

	Ara	Dut	Jap	Slo	Spa	Tur	AV
P	71.74	78.83	91.78	78.66	81.19	71.70	79.05
E	72.99	**79.69**	**92.18**	**80.10**	**81.93**	72.02	**79.82**
L	**73.67**	79.55	91.49	79.66	81.57	**72.26**	79.71

Table 3: Results for the three training algorithms on the different languages (P = perceptron, E = EG, L = log-linear models). AV is an average across the results for the different languages.

averaged perceptron has a single meta-parameter, namely the number of iterations over the training set. The log-linear models have two meta-parameters: the regularization constant C and the number of gradient steps T taken by the conjugate-gradient optimizer. The EG approach also has two meta-parameters: the regularization constant C and the number of iterations, T.[6] For models trained using non-projective algorithms, both projective and non-projective parsing was tested on the validation set, and the highest scoring of these two approaches was then used to decode test data sentences.

Table 2 reports test results for the six training scenarios. These results show that for Dutch, which is the language in our data that has the highest number of crossing dependencies, non-projective training gives significant gains over projective training for all three training methods. For the other languages, non-projective training gives similar or even improved performance over projective training.

Table 3 gives an additional set of results, which were calculated as follows. For each of the three training methods, we used the validation set results to choose between projective and non-projective training. This allows us to make a direct comparison of the three training algorithms. Table 3 shows the results of this comparison.[7] The results show that log-linear and max-margin models both give a higher average accuracy than the perceptron. For some languages (e.g., Japanese), the differences from the perceptron are small; however for other languages (e.g., Arabic, Dutch or Slovene) the improvements seen are quite substantial.

7 Conclusions

This paper describes inference algorithms for spanning-tree distributions, focusing on the fundamental problems of computing partition functions and marginals. Although we concentrate on log-linear and max-margin estimation, the inference algorithms we present can serve as black-boxes in many other statistical modeling techniques.

Our experiments suggest that marginal-based training produces more accurate models than perceptron learning. Notably, this is the first large-scale application of the EG algorithm, and shows that it is a promising approach for structured learning.

In line with McDonald et al. (2005b), we confirm that spanning-tree models are well-suited to dependency parsing, especially for highly non-projective languages such as Dutch. Moreover, spanning-tree models should be useful for a variety of other problems involving structured data.

[6] We trained the perceptron for 100 iterations, and chose the iteration which led to the best score on the validation set. Note that in all of our experiments, the best perceptron results were actually obtained with 30 or fewer iterations. For the log-linear and EG algorithms we tested a number of values for C, and for each value of C ran 100 gradient steps or EG iterations, finally choosing the best combination of C and T found in validation.

[7] We ran the sign test at the sentence level to measure the statistical significance of the results aggregated across the six languages. Out of 2,472 sentences total, log-linear models gave improved parses over the perceptron on 448 sentences, and worse parses on 343 sentences. The max-margin method gave improved/worse parses for 500/383 sentences. Both results are significant with $p \leq 0.001$.

Using Foreign Inclusion Detection to Improve Parsing Performance

Abstract

Inclusions from other languages can be a significant source of errors for monolingual parsers. We show this for English inclusions, which are sufficiently frequent to present a problem when parsing German. We describe an annotation-free approach for accurately detecting such inclusions, and develop two methods for interfacing this approach with a state-of-the-art parser for German. An evaluation on the TIGER corpus shows that our inclusion entity model achieves a performance gain of 4.3 points in F-score over a baseline of no inclusion detection, and even outperforms a parser with access to gold standard part-of-speech tags.

1 Introduction

The status of English as a global language means that English words and phrases are frequently borrowed by other languages, especially in domains such as science and technology, commerce, advertising, and current affairs. This is an instance of *language mixing*, whereby inclusions from other languages appear in an otherwise monolingual text. While the processing of foreign inclusions has received some attention in the text-to-speech (TTS) literature (see Section 2), the natural language processing (NLP) community has paid little attention both to the problem of inclusion detection, and to potential applications thereof. Also the extent to which inclusions pose a problem to existing NLP methods has not been investigated.

In this paper, we address this challenge. We focus on English inclusions in German text. Anglicisms and other borrowings from English form by far the most frequent foreign inclusions in German. In specific domains, up to 6.4% of the tokens of a German text can be English inclusions. Even in regular newspaper text as used for many NLP applications, English inclusions can be found in up to 7.4% of all sentences (see Section 3 for both figures).

Virtually all existing NLP algorithms assume that the input is monolingual, and does not contain foreign inclusions. It is possible that this is a safe assumption, and inclusions can be dealt with accurately by existing methods, without resorting to specialized mechanisms. The alternative hypothesis, however, seems more plausible: foreign inclusions pose a problem for existing approaches, and sentences containing them are processed less accurately. A parser, for example, is likely to have problems with inclusions – most of the time, they are unknown words, and as they originate from another language, standard methods for unknown words guessing (suffix stripping, etc.) are unlikely to be successful. Furthermore, the fact that inclusions are often multiword expressions (e.g., named entities) means that simply part-of-speech (POS) tagging them accurately is not sufficient: if the parser posits a phrase boundary within an inclusion this is likely to severely decrease parsing accuracy.

In this paper, we focus on the impact of English inclusions on the parsing of German text. We describe an annotation-free method that accurately recognizes English inclusions, and demonstrate that inclusion detection improves the performance of a state-of-the-art parser for German. We show that the way of interfacing the inclusion detection and the parser is crucial, and propose a method for modifying the underlying probabilistic grammar in order to

Proceedings of the 2007 Joint Conference on Empirical Methods in Natural Language Processing and Computational Natural Language Learning, pp. 151–160, Prague, June 2007.

enable the parser to process inclusions accurately.

This paper is organized as follows. We review related work in Section 2, and present the English inclusion classifier in Section 3. Section 4 describes our results on interfacing inclusion detection with parsing, and Section 5 presents an error analysis. Discussion and conclusion follow in Section 6.

2 Related Work

Previous work on inclusion detection exists in the TTS literature. Here, the aim is to design a system that recognizes foreign inclusions on the word and sentence level and functions at the front-end to a polyglot TTS synthesizer. Pfister and Romsdorfer (2003) propose morpho-syntactic analysis combined with lexicon lookup to identify foreign words in mixed-lingual text. While they state that their system is precise at detecting the language of tokens and determining the sentence structure, it is not evaluated on real mixed-lingual text. A further approach to inclusion detection is that of Marcadet et. al (2005). They present experiments with a dictionary-driven transformation-based learning method and a corpus-based n-gram approach and show that a combination of both methods yields the best results. Evaluated on three mixed-lingual test sets in different languages, the combined approach yields word-based language identification error rates (i.e. the percentage of tokens for which the language is identified incorrectly) of 0.78% on the French data, 1.33% on the German data and 0.84% on the Spanish data. Consisting of 50 sentences or less for each language, their test sets are very small and appear to be selected specifically for evaluation purposes. It would therefore be interesting to determine the system's performance on random and unseen data and examine how it scales up to larger data sets.

Andersen (2005), noting the importance of recognizing anglicisms to lexicographers, tests algorithms based on lexicon lookup, character n-grams and regular expressions and a combination thereof to automatically extract anglicisms in Norwegian text. On a 10,000 word subset of the neologism archive (Wangensteen, 2002), the best method of combining character n-grams and regular expression matching yields an accuracy of 96.32% and an F-score of 59.4 (P = 75.8%, R = 48.8%). This result is unsurprisingly low as no differentiation is made between full-word anglicisms and tokens with mixed-lingual morphemes in the gold standard.

In the context of parsing, Forst and Kaplan (2006) have observed that the failure to properly deal with foreign inclusions is detrimental to a parser's accuracy. However, they do not substantiate this claim using numeric results.

3 English Inclusion Detection

Previous work reported by Alex (2006; 2005) has focused on devising a classifier that detects anglicisms and other English inclusions in text written in other languages, namely German and French. This inclusion classifier is based on a lexicon and search engine lookup as well as a post-processing step.

The lexicon lookup is performed for tokens tagged as noun (*NN*), named entity (*NE*), foreign material (*FM*) or adjective (*ADJA/ADJD*) using the German and English CELEX lexicons. Tokens only found in the English lexicon are classified as English. Tokens found in neither lexicon are passed to the search engine module. Tokens found in both databases are classified by the post-processing module. The search engine module performs language classification based on the maximum normalised score of the number of hits returned for two searches per token, one for each language (Alex, 2005). This score is determined by weighting the number of hits, i.e. the "absolute frequency" by the estimated size of the accessible Web corpus for that language (Alex, 2006). Finally, the rule-based post-processing module classifies single-character tokens and resolves language classification ambiguities for interlingual homographs, English function words, names of currencies and units of measurement. A further post-processing step relates language information between abbreviations or acronyms and their definitions in combination with an abbreviation extraction algorithm (Schwartz and Hearst, 2003). Finally, a set of rules disambiguates English inclusions from person names (Alex, 2006).

For German, the classifier has been evaluated on test sets in three different domains: newspaper articles, selected from the Frankfurter Allgemeine Zeitung, on internet and telecoms, space travel and European Union related topics. Table 1 presents an

Domain	EI tokens	EI types	EI TTR	Accuracy	Precision	Recall	F
Internet	6.4%	5.9%	0.25	98.13%	91.58%	78.92%	84.78
Space	2.8%	3.5%	0.33	98.97%	84.02%	85.31%	84.66
EU	1.1%	2.1%	0.50	99.65%	82.16%	87.36%	84.68

Table 1: English inclusion (EI) token and type statistics, EI type-token-ratios (TTR) as well as accuracy, precision, recall and F-scores for the unseen German test sets.

overview of the percentages of English inclusion tokens and types within the gold standard annotation of each test set, and illustrates how well the English inclusion classifier is able to detect them in terms of F-score. The figures show that the frequency of English inclusions varies considerably depending on the domain but that the classifier is able to detect them equally well with an F-score approaching 85 for each domain.

The recognition of English inclusions bears similarity to classification tasks such as named entity recognition, for which various machine learning (ML) techniques have proved successful. In order to compare the performance of the English inclusion classifier against a trained ML classifier, we pooled the annotated English inclusion evaluation data for all three domains. As the English inclusion classifier does not rely on annotated data, it can be tested and evaluated once for the entire corpus. The ML classifier used for this experiment is a conditional Markov model tagger which is designed for, and proved successful in, named entity recognition in newspaper and biomedical text (Klein et al., 2003; Finkel et al., 2005). It can be trained to perform similar information extraction tasks such as English inclusion detection. To determine the tagger's performance over the entire set and to investigate the effect of the amount of annotated training data available, a 10-fold cross-validation test was conducted whereby increasing sub-parts of the training data are provided when testing on each fold. The resulting learning curves in Figure 1 show that the English inclusion classifier has an advantage over the supervised ML approach, despite the fact the latter requires expensive hand-annotated data. A large training set of 80,000 tokens is required to yield a performance that approximates that of our annotation-free inclusion classifier. This system has been shown to perform similarly well on unseen texts in different domains, plus it is easily extendable to a new language (Alex, 2006).

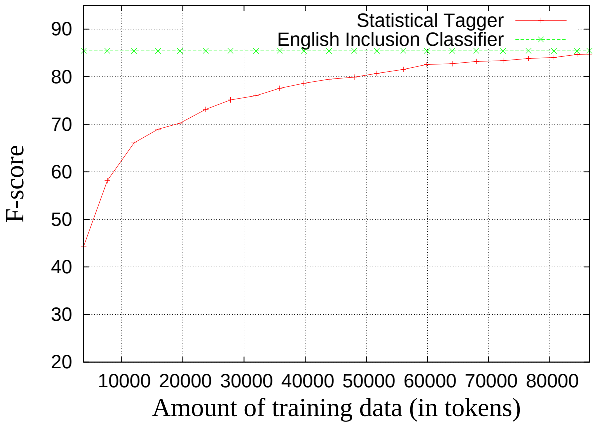

Figure 1: Learning curve of a ML classifier versus the English inclusion classifier's performance.

4 Experiments

The primary focus of this paper is to apply the English inclusion classifier to the German TIGER treebank (Brants et al., 2002) and to evaluate the classifier on a standard NLP task, namely parsing. The aim is to investigate the occurrence of English inclusions in more general newspaper text, and to examine if the detection of English inclusions can improve parsing performance.

The TIGER treebank is a bracketed corpus consisting of 40,020 sentences of newspaper text. The English inclusion classifier was run once over the entire TIGER corpus. In total, the system detected English inclusions in 2,948 of 40,020 sentences (7.4%), 596 of which contained at least one multi-word inclusion. This subset of 596 sentences is the focus of the work reported in the remainder of this paper, and will be referred to as the inclusion set.

A gold standard parse tree for a sentence containing a typical multi-word English inclusion is illustrated in Figure 2. The tree is relatively flat, which is a trait trait of TIGER treebank annotation (Brants et al., 2002). The non-terminal nodes of the tree represent the phrase categories, and the edge labels the grammatical functions. In the example sentence, the English inclusion is contained in a proper noun (*PN*) phrase with a grammatical function of type noun kernel element (*NK*). Each terminal node is POS-tagged as a named entity (*NE*) with the grammatical function ot type proper noun component (*PNC*).

4.1 Data

Two different data sets are used in the experiments: (1) the inclusion set, i.e., the sentences containing multi-word English inclusions recognized by the inclusion classifier, and (2) a stratified sample of sentences randomly extracted from the TIGER corpus, with strata for different sentence lengths. The strata were chosen so that the sentence length distribution of the random set matches that of the inclusion set. The average sentence length of this random set and the inclusion set is therefore the same at 28.4 tokens. This type of sampling is necessary as the inclusion set has a higher average sentence length than a random sample of sentences from TIGER, and because parsing accuracy is correlated with sentence length. Both the inclusion set and the random set consist of 596 sentences and do not overlap.

4.2 Parser

The parsing experiments were performed with a state-of-the-art parser trained on the TIGER corpus which returns both phrase categories and grammatical functions (Dubey, 2005b). Following Klein and Manning (2003), the parser uses an unlexicalized probabilistic context-free grammar (PCFG) and relies on treebank transformations to increase parsing accuracy. Crucially, these transformations make use of TIGER's grammatical functions to relay pertinent lexical information from lexical elements up into the tree.

The parser also makes use of suffix analysis. However, beam search or smoothing are not employed. Based upon an evaluation on the NEGRA treebank (Skut et al., 1998), using a 90%-5%-5% training-development-test split, the parser performs with an accuracy of 73.1 F-score on labelled brackets with a coverage of 99.1% (Dubey, 2005b). These figures were derived on a test set limited to sentences containing 40 tokens or less. In the data set used in this paper, however, sentence length is not limited. Moreover, the average sentence length of our test sets is considerably higher than that of the NEGRA test set. Consequently, a slightly lower performance and/or coverage is anticipated, albeit the type and domain as well as the annotation of both the NEGRA and the TIGER treebanks are very similar. The minor annotation differences that do exist between NEGRA and TIGER are explained in Brants et. al (2002).

4.3 Parser Modifications

We test several variations of the parser. The **baseline** parser does not treat foreign inclusions in any special way: the parser attempts to guess the POS tag and grammatical function labels of the word using the same suffix analysis as for rare or unseen German words. The additional versions of the parser are inspired by the hypothesis that inclusions make parsing difficult, and this difficulty arises primarily because the parser cannot detect inclusions properly. Therefore, a suitable upper bound is to give the parser **perfect tagging** information. Two further versions interface with our inclusion classifier and treat words marked as inclusions differently from native words. The first version does so on a **word-by-word** basis. In contrast, the **inclusion entity** approach attempts to group inclusions, even if a grouping is not posited by phrase structure rules. We now describe each version in more detail.

In the TIGER annotation, preterminals include both POS tags and grammatical function labels. For example, rather than a preterminal node having the category *PRELS* (personal pronoun), it is given the category *PRELS-OA* (accusative personal pronoun). Due to these grammatical function tags, the perfect tagging parser may disambiguate more syntactic information than provided with POS tags alone. Therefore, to make this model more realistic, the parser is required to guess grammatical functions (allowing it to, for example, mistakenly tag an accusative pronoun as nominative, dative or genitive). This gives the parser information about the POS tags of English inclusions (along with other words), but does not give any additional hints about the syntax of the sentence.

The two remaining models both take advantage

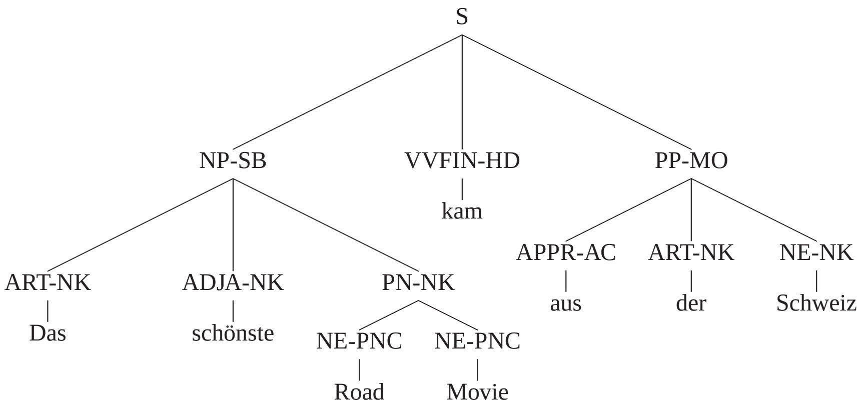

Figure 2: Example parse tree of a German TIGER sentence containing an English inclusion. Translation: The nicest road movie came from Switzerland.

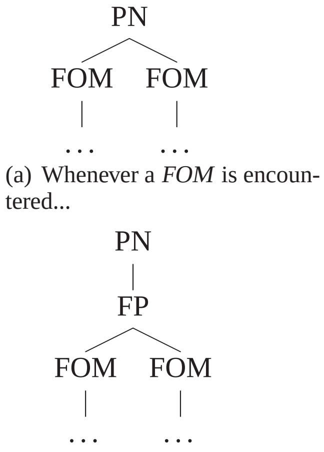
Table 2: POS tags of foreign inclusions.



(a) Whenever a *FOM* is encountered...

(b) ...a new *FP* category is created

Figure 3: Tree transformation employed in the *inclusion entity* parser.

of information from the inclusion detector. To interface the detector with the parser, we simply mark any inclusion with a special *FOM* (foreign material) tag. The word-by-word parser attempts to guess POS tags itself, much like the baseline. However, whenever it encounters a *FOM* tag, it restricts itself to the set of POS tags observed in inclusions during training (the tags listed in Table 2). When a *FOM* is detected, these and only these POS tags are guessed; all other aspects of the parser remain the same.

The word-by-word parser fails to take advantage of one important trend in the data: that foreign inclusion tokens tend to be adjacent, and these adjacent words usually refer to the same entity. There is nothing stopping the word-by-word parser from positing a constituent boundary between two adjacent foreign inclusions. The inclusion entity model was developed to restrict such spurious bracketing. It does so by way of another tree transformation. The new category *FP* (foreign phrase) is added below any node dominating at least one token marked *FOM* during training. For example, when encountering a *FOM* sequence dominated by *PN* as in Figure 3(a), the tree is modified so that it is the *FP* rule which generates the *FOM* tokens. Figure 3(b) shows the modified tree. In all cases, a unary rule *PN*→FP is introduced. As this extra rule decreases the probability of the entire tree, the parser has a bias to introduce as few of these rules as possible – thus limiting the number of categories which expand to *FOM*s. Once a candidate parse is created during testing, the inverse operation is applied, removing the *FP* node.

4.4 Method

For all experiments reported in this paper, the parser is trained on the TIGER treebank. As the inclusion and random sets are drawn from the whole TIGER treebank, it is necessary to ensure that the data used to train the parser does not overlap with these test sentences. The experiments are therefore designed as multifold cross-validation tests. Using 5 folds, each model is trained on 80% of the data while the remaining 20% are held out. The held out set is then

Data	P	R	F	Dep.	Cov.	AvgCB	0CB	≤2CB
Baseline model								
Inclusion set	56.1	62.6	59.2	74.9	99.2	2.1	34.0	69.0

Table 3: Baseline and perfect tagging for inclusion and random sets and results for the word-by-word and the inclusion entity models.

intersected with the inclusion set (or, respectively, the random set). The evaluation metrics are calculated on this subset of the inclusion set (or random set), using the parser trained on the corresponding training data. This process ensures that the test sentences are not contained in the training data.

The overall performance metrics of the parser are calculated on the aggregated totals of the five held out test sets. For each experiment, we report parsing performance in terms of the standard PARSEVAL scores (Abney et al., 1991), including coverage (Cov), labeled precision (P) and recall (R), F-score, the average number of crossing brackets (AvgCB), and the percentage of sentences parsed with zero and with two or fewer crossing brackets (0CB and ≤2CB). In addition, we also report dependency accuracy (Dep), calculated using the approach described in Lin (1995), using the head-picking method used by Dubey (2005a). The labeled bracketing figures (P, R and F), and the dependency score are calculated on all sentences, with those which are out-of-coverage getting zero nodes. The crossing bracket scores are calculated only on those sentences which are successfully parsed.

4.5 Baseline and Perfect Tagging

The baseline, for which the unmodified parser is used, achieves a high coverage at over 99% for both the inclusion and the random sets (see Table 3). However, scores differ for the bracketing measures. Using stratified shuffling[1], we performed a *t*-test on precision and recall, and found both to be significantly worse in the inclusion condition. Overall, the harmonic mean (F) of precision and recall was 65.2 on the random set, 6 points better than 59.2 F observed on the inclusion set. Similarly, dependency and cross-bracketing scores are higher on the random test set. This result strongly indicates that sentences containing English inclusions present difficulty for the parser, compared to length-matched sentences without inclusions.

When providing the parser with perfect tagging information, scores improve both for the inclusion and the random TIGER samples, resulting in F-scores of 62.2 and 67.3, respectively. However, the coverage for the inclusion set decreases to 92.7% whereas the coverage for the random set is 97.7%. In both cases, the lower coverage is caused by the parser being forced to use infrequent tag sequences, with the much lower coverage of the inclusion set likely due to infrequent tags (notable *FM*), solely associated with inclusions. While perfect tagging increases overall accuracy, a difference of 5.1 in F-score remains between the random and inclusion test sets. Although smaller than that of the baseline runs, this difference shows that even with perfect tagging,

[1] This approach to statistical testing is described in: `http://www.cis.upenn.edu/~dbikel/software.html`

parsing English inclusions is harder than parsing monolingual data.

So far, we have shown that the English inclusion classifier is able to detect sentences that are difficult to parse. We have also shown that perfect tagging helps to improve parsing performance but is insufficient when it comes to parsing sentences containing English inclusions. In the next section, we will examine how the knowledge provided by the English inclusion classifier can be exploited to improve parsing performance for such sentences.

4.6 Word-by-word Model

The word-by-word model achieves the same coverage on the inclusion set as the baseline but with a slightly lower F of 59.0. All other scores, including dependency accuracy and cross bracketing results are similar to those of the baseline (see Table 3). This shows that limiting the parser's choice of POS tags to those encountered for English inclusions is not sufficient to deal with such constructions correctly. In the error analysis presented in Section 5, we report that the difficulty in parsing multi-word English inclusions is recognizing them as constituents, rather than recognizing their POS tags. We attempt to overcome this problem with the inclusion entity model.

4.7 Inclusion Entity Model

The inclusion entity parser attains a coverage of 99.0% on the inclusion set, similiar to the coverage of 99.2% obtained by the baseline model on the same data. On all other measures, the inclusion entity model exceeds the performance of the baseline, with a precision of 61.3% (5.2% higher than the baseline), a recall of 65.9% (3.3% higher), an F of 63.5 (4.3 higher) and a dependency accuracy of 78.3% (3.4% higher). The average number of crossing brackets is 1.7 (0.4 lower), with 42.4% of the parsed sentences having no crossing brackets (8.2% higher), and 77.1% having two or fewer crossing brackets (8.1% higher). When testing the inclusion entity model on the random set, the performance is very similar to the baseline model on this data. While coverage is the same, F and cross-brackting scores are marginally improved, and the dependency score is marginally deteriorated. This shows that the inclusion entity model does not harm the parsing accuracy of sentences that do not actually contain foreign inclusions.

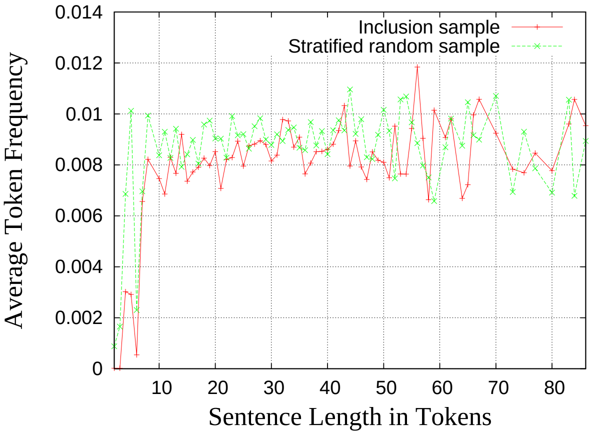

Figure 4: Average relative token frequencies for sentences of equal length.

Not only did the inclusion entity parser perform above the baseline on every metric for the inclusion set, its performance also exceeds that of the perfect tagging model on all measures except precision and average crossing brackets, where both models are tied. These results clearly indicate that the inclusion entity model is able to leverage the additional information about English inclusions provided by our inclusion classifier. However, it is also important to note that the performance of this model on the inclusion set is still consistently lower than that of all models on the random set. This demonstrates that sentences with inclusions are more difficult to parse than monolingual sentences, even in the presence of information about the inclusions that the parser can exploit.

Comparing the inclusion set to the length-matched random set is arguably not entirely fair as the latter may not contain as many infrequent tokens as the inclusion set. Figure 4 shows the average relative token frequencies for sentences of equal length for both sets. The frequency profiles of the two data sets are broadly similar (the difference in means of both groups is only 0.000676), albeit significantly different according to a paired t-test ($p \leq 0.05$). This is one reason why the inclusion entity model's performance on the inclusion set does not reach the upper limit set by the random sample.

Phrase cat.	Frequency	Example
PN	91	The Independent
CH	10	Made in Germany
NP	4	Peace Enforcement
CNP	2	Botts and Company
–	2	Chief Executives

Table 4: Gold phrase categories of inclusions.

Phrase bracket (PB) frequency	BL	IE
$PB_{PRED} > PB_{GOLD}$	62%	51%
$PB_{PRED} < PB_{GOLD}$	11%	13%
$PB_{PRED} = PB_{GOLD}$	27%	36%

Table 5: Bracket frequency of the predicted baseline (BL) and inclusion entity (IE) model output compared to the gold standard.

5 Error Analysis

The error analysis is limited to 100 sentences selected from the inclusion set parsed with both the baseline and the inclusion entity model. This sample contains 109 English inclusions, five of which are false positives, i.e., the output of the English inclusion classifier is incorrect. The precision of the classifier in recognizing multi-word English inclusions is therefore 95.4% for this TIGER sample.

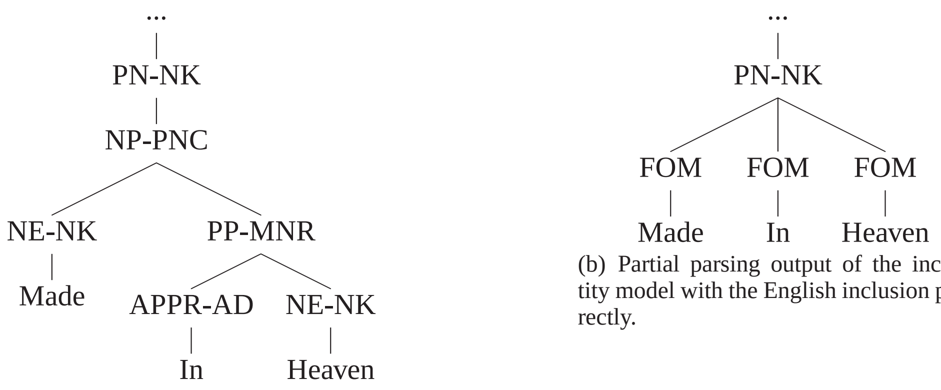
Table 4 illustrates that the majority of multi-word English inclusions are contained in a proper noun (*PN*) phrase, including names of companies, political parties, organizations, films, newspapers, etc. A less frequent phrasal category is chunk (*CH*) which tends to be used for slogans, quotes or expressions like *Made in Germany*. Even in this small sample, annotations of inclusions as either *PN* or *CH*, and not the other, can be misleading. For example, the organization *Friends of the Earth* is annotated as a *PN*, whereas another organization *International Union for the Conservation of Nature* is marked as a *CH* in the gold standard. This suggests that the annotation guidelines on foreign inclusions could be improved when differentiating between phrase categories containing foreign material.

For the majority of sentences (62%), the baseline model predicts more brackets than are present in the gold standard parse tree (see Table 5). This number decreases by 11% to 51% when parsing with the inclusion entity model. This suggests that the baseline parser does not recognize English inclusions as constituents, and instead parses their individual tokens as separate phrases. Provided with additional information of multi-word English inclusions in the training data, the parser is able to overcome this problem.

We now turn our attention to how accurately the various parsers are at predicting both phrase bracketing and phrase categories (see Table 6). For 46 (42.2%) of inclusions, the baseline model makes an error with a negative effect on performance. In 39 cases (35.8%), the phrase bracketing and phrase category are incorrect, and constituent boundaries occur within the inclusion, as illustrated in Figure 5(a). Such errors also have a detrimental effect on the parsing of the remainder of the sentence. Overall, the baseline model predicts the correct phrase bracketing and phrase category for 63 inclusions (57.8%). Conversely, the inclusion entity model, which is given information on tag consistency within inclusions via the *FOM* tags, is able to determine the correct phrase bracketing and phrase category for 67.9% inclusions (10.1% more), e.g. see Figure 5(b). Both the phrase bracketing and phrase category are predicted incorrectly in only 6 cases (5.5%). The inclusion entity model's improved phrase boundary prediction for 31 inclusions (28.4% more correct) is likely to have an overall positive effect on the parsing decisions made for the context which they appear in. Nevertheless, the inclusion entity parser still has difficulty determining the correct phrase category in 25 cases (22.9%). The main confusion lies between assigning the categories *PN*, *CH* and *NP*, the most frequent phrase categories of multi-word English inclusions. This is also partially due to the ambiguity between these phrases in the gold standard. Finally, few parsing errors (4) are caused by the inclusion entity parser due to the markup of false positive inclusions (mainly boundary errors).

6 Discussion and Conclusion

This paper has argued that English inclusions in German text is an increasingly pervasive instance of language mixing. Starting with the hypothesis that such inclusions can be a significant source of errors for monolingual parsers, we found evidence that an unmodified state-of-the-art parser for Ger-



(a) Partial parsing output of the baseline model with a constiuent boundary in the English inclusion.

(b) Partial parsing output of the inclusion entity model with the English inclusion parsed correctly.

Parser: inclusion entity model, data: inclusion set	
Incorrect PB and PC	6 (5.5%)
Incorrect PC	25 (22.9%)
Incorrect PB	4 (3.7%)
Correct PB and PC	74 (67.9%)

Table 6: Baseline and inclusion entity model errors for inclusions with respect to their phrase bracketing (PB) and phrase category (PC).

man performs substantially worse on a set of sentences with English inclusions compared to a set of length-matched sentences randomly sampled from the same corpus. The lower performance on the inclusion set persisted even when the parser when given gold standard POS tags in the input.

To overcome the poor accuracy of parsing inclusions, we developed two methods for interfacing the parser with an existing annotation-free inclusion detection system. The first method restricts the POS tags for inclusions that the parser can assign to those found in the data. The second method applies tree transformations to ensure that inclusions are treated as phrases. An evaluation on the TIGER corpus shows that the second method yields a performance gain of 4.3 in F-score over a baseline of no inclusion detection, and even outperforms a model involving perfect POS tagging of inclusions.

To summarize, we have shown that foreign inclusions present a problem for a monolingual parser. We also demonstrated that it is insufficient to know where inclusions are or even what their parts of speech are. Parsing performance only improves if the parser also has knowledge about the structure of the inclusions. It is particularly important to know when adjacent foreign words are likely to be part of the same phrase. As our error analysis showed, this prevents cascading errors further up in the parse tree.

Finally, our results indicate that future work could improve parsing performance for inclusions further: we found that parsing the inclusion set is still harder than parsing a randomly sampled test set, even for our best-performing model. This provides an upper bound on the performance we can expect from a parser that uses inclusion detection. Future work will also involve determining the English inclusion classifier's merit when applied to rule-based parsing.

LEDIR: An Unsupervised Algorithm for Learning Directionality of Inference Rules

Rahul Bhagat, Patrick Pantel, Eduard Hovy

Abstract

Semantic inference is a core component of many natural language applications. In response, several researchers have developed algorithms for automatically learning inference rules from textual corpora. However, these rules are often either imprecise or underspecified in directionality. In this paper we propose an algorithm called LEDIR that filters incorrect inference rules and identifies the directionality of correct ones. Based on an extension to Harris's distributional hypothesis, we use selectional preferences to gather evidence of inference directionality and plausibility. Experiments show empirical evidence that our approach can classify inference rules significantly better than several baselines.

1 Introduction

Paraphrases are textual expressions that convey the same meaning using different surface forms. Textual entailment is a similar phenomenon, in which the presence of one expression licenses the validity of another. Paraphrases and inference rules are known to improve performance in various NLP applications like Question Answering (Harabagiu and Hickl 2006), summarization (Barzilay et al. 1999) and Information Retrieval (Anick and Tipirneni 1999).

Paraphrase and entailment involve inference rules that license a conclusion when a premise is given. Deciding whether a proposed inference rule is fully valid is difficult, however, and most NL systems instead focus on plausible inference. In this case, one statement has some likelihood of being identical in meaning to, or derivable from, the other. In the rest of this paper we discuss plausible inference only.

Given the importance of inference, several researchers have developed inference rule collections. While manually built resources like WordNet (Fellbaum 1998) and Cyc (Lenat 1995) have been around for years, for coverage and domain adaptability reasons many recent approaches have focused on automatic acquisition of paraphrases (Barzilay and McKeown 2001) and inference rules (Lin and Pantel 2001; Szpektor et al. 2004). The downside of these approaches is that they often result in incorrect inference rules or in inference rules that are underspecified in directionality (i.e. asymmetric but are wrongly considered symmetric). For example, consider an inference rule from DIRT (Lin and Pantel 2001):

$$X\ eats\ Y \Leftrightarrow X\ likes\ Y \qquad (1)$$

All rules in DIRT are considered symmetric. Though here, one is most likely to infer that "*X eats Y*" ⇒ "*X likes Y*", because if someone eats something, he most probably likes it[1], but if he likes something he might not necessarily be able to eat it. So for example, given the sentence "*I eat spicy food*", one is mostly likely to infer that "*I like spicy food*". On the other hand, given the sentence "*I like rollerblading*", one cannot infer that "*I eat rollerblading*".

In this paper, we propose an algorithm called **LEDIR** (pronounced "leader") for **LE**arning **Di**rectionality of **I**nference **R**ules. Our algorithm filters incorrect inference rules and identifies the directionality of the correct ones. Our algorithm

[1] There could be certain usages of "*X eats Y*" where, one might not be able to infer "*X likes Y*" (for example metaphorical). But, in most cases, this inference holds.

Proceedings of the 2007 Joint Conference on Empirical Methods in Natural Language Processing and Computational Natural Language Learning, pp. 161–170, Prague, June 2007. ©2007 Association for Computational Linguistics

works with any resource that produces inference rules of the form shown in example (1). We use both the distributional hypothesis and selectional preferences as the basis for our algorithm. We provide empirical evidence to validate the following main contribution:

***Claim**: Relational selectional preferences can be used to automatically determine the plausibility and directionality of an inference rule.*

2 Related Work

In this section, we describe applications that can benefit by using inference rules and their directionality. We then talk about some previous work in this area.

2.1 Applications

Open domain question answering approaches often cast QA as the problem of finding some kind of semantic inference between a question and its answer(s) (Moldovan et al. 2003; Echiabi and Marcu 2003). Harabagiu and Hickl (2006) recently demonstrated that textual entailment inference information, which in this system is a set of directional inference relations, improves the performance of a QA system significantly even without using any other form of semantic inference. This evidence supports the idea that learning the directionality of other sets of inference rules may improve QA performance.

In Multi-Document Summarization (MDS), paraphrasing is useful for determining sentences that have similar meanings (Barzilay et al. 1999). Knowing the directionality between the inference rules here could allow the MDS system to choose either the more specific or general sentence depending on the purpose of the summary.

In IR, paraphrases have been used for query expansion, which is known to promote effective retrieval (Anick and Tipirneni 1999). Knowing the directionality of rules here could help in making a query more general or specific depending on the user needs.

2.2 Learning Inference Rules

Automatically learning paraphrases and inference rules from text is a topic that has received much attention lately. Barzilay and McKeown (2001) for paraphrases, DIRT (Lin and Pantel 2001) and TEASE (Szpektor et al. 2004) for inference rules, are recent approaches that have achieved promising results. While all these approaches produce collections of inference rules that have good recall, they suffer from the complementary problem of low precision. They also make no attempt to distinguish between symmetric and asymmetric inference rules. Given the potential positive impact shown in Section 2.1 of learning the directionality of inference rules, there is a need for methods, such as the one we present, to improve existing automatically created resources.

2.3 Learning Directionality

There have been a few approaches at learning the directionality of restricted sets of semantic relations, mostly between verbs. Chklovski and Pantel (2004) used lexico-syntactic patterns over the Web to detect certain types of symmetric and asymmetric relations between verbs. They manually examined and obtained lexico-syntactic patterns that help identify the types of relations they considered and used these lexico-syntactic patterns over the Web to detect these relations among a set of candidate verb pairs. Their approach however is limited only to verbs and to specific types of verb-verb relations.

Zanzotto et al. (2006) explored a selectional preference-based approach to learn asymmetric inference rules between verbs. They used the selectional preferences of a single verb, i.e. the semantic types of a verb's arguments, to infer an asymmetric inference between the verb and the verb form of its argument type. Their approach however applies also only to verbs and is limited to some specific types of verb-argument pairs.

Torisawa (2006) presented a method to acquire inference rules with temporal constraints, between verbs. They used co-occurrences between verbs in Japanese coordinated sentences and co-occurrences between verbs and nouns to learn the verb-verb inference rules. Like the previous two methods, their approach too deals only with verbs and is limited to learning inference rules that are temporal in nature.

Geffet and Dagan (2005) proposed an extension to the distributional hypothesis to discover entailment relation between words. They model the context of a word using its syntactic features and compare the contexts of two words for strict inclusion to infer lexical entailment. In principle, their work is the most similar to ours. Their method however is limited to lexical entailment and they show its effectiveness for nouns. Our method on the other hand deals with inference rules between binary relations and includes inference rules between verbal relations, non-verbal relations and multi-word relations. Our definition of context and the methodology for obtaining context similarity and overlap is also much different from theirs.

3 Learning Directionality of Inference Rules

The aim of this paper is to filter out incorrect inference rules and to identify the directionality of the correct ones.

Let $p_i \Leftrightarrow p_j$ be an inference rule where each p is a binary semantic relation between two entities x and y. Let $<x, p, y>$ be an instance of relation p.

Formal problem definition: *Given the inference rule $p_i \Leftrightarrow p_j$, we want to conclude which one of the following is more appropriate:*

1. $p_i \Leftrightarrow p_j$
2. $p_i \Rightarrow p_j$
3. $p_i \Leftarrow p_j$
4. *No plausible inference*

Consider the example (1) from section 1. There, it is most plausible to conclude "*X eats Y*" ⇒ "*X likes Y*".

Our algorithm LEDIR uses selectional preferences along the lines of Resnik (1996) and Pantel et al. (2007) to determine the plausibility and directionality of inference rules.

3.1 Underlying Assumption

Many approaches to modeling lexical semantics have relied on the distributional hypothesis (Harris 1954), which states that words that appear in the same contexts tend to have similar meanings. The idea is that context is a good indicator of a word meaning. Lin and Pantel (2001) proposed an extension to the distributional hypothesis and applied it to paths in dependency trees, where if two paths tend to occur in similar contexts it is hypothesized that the meanings of the paths tend to be similar.

In this paper, we assume and propose a further extension to the distributional hypothesis and call it the "Directionality Hypothesis".

Directionality Hypothesis: *If two binary semantic relations tend to occur in similar contexts and the first one occurs in significantly more contexts than the second, then the second most likely implies the first and not vice versa.*

The intuition here is that of generality. The more general a relation, more the types (and number) of contexts in which it is likely to appear. Consider the example (1) from section 1. The fact is that there are many more things that someone might like than those that someone might eat. Hence, by applying the directionality hypothesis, one can infer that "*X eats Y*" ⇒ "*X likes Y*".

The key to applying the distributional hypothesis to the problem at hand is to model the contexts appropriately and to introduce a measure for calculating context similarity. Concepts in semantic space, due to their abstractive power, are much richer for reasoning about inferences than simple surface words. Hence, we model the context of a relation p of the form $<x, p, y>$ by using the semantic classes *C(x)* and *C(y)* of words that can be instantiated for x and y respectively. To measure context similarity of two relations, we calculate the overlap coefficient (Manning and Schütze, 1999) between their contexts.

3.2 Selectional Preferences

The selectional preferences of a predicate is the set of semantic classes that its arguments can belong to (Wilks 1975). Resnik (1996) gave an information theoretical formulation of the idea. Pantel et al. (2007) extended this idea to non-verbal relations by defining the relational selectional preferences (RSPs) of a binary relation p as the set of semantic classes $C(x)$ and $C(y)$ of words that can occur in positions x and y respectively.

The set of semantic classes $C(x)$ and $C(y)$ can be obtained either from a manually created taxonomy like WordNet as proposed in the above previous approaches or by using automatically generated classes from the output of a word clustering algorithm as proposed in Pantel et al. (2007). For example given a relation like "*X likes Y*", its RSPs from WordNet could be *{individual, social_group…}* for *X* and *{individual, food, activity…}* for *Y*.

In this paper, we deployed both the Joint Relational Model (JRM) and Independent Relational Model (IRM) proposed by Pantel et al. (2007) to obtain the selectional preferences for a relation p.

Model 1: Joint Relational Model (JRM)

The JRM uses a large corpus to learn the selectional preferences of a binary semantic relation by considering its arguments jointly.

Given a relation *p* and large corpus of English text, we first find all occurrences of relation *p* in the corpus. For every instance <*x, p, y*> in the corpus, we obtain the sets *C*(*x*) and *C*(*y*) of the semantic classes that *x* and *y* belong to. We then accumulate the frequencies of the triples <*c*(*x*), *p*, *c*(*y*)> by assuming that every $c(x) \in C(x)$ can co-occur with every $c(y) \in C(y)$ and vice versa. Every triple <*c*(*x*), *p*, *c*(*y*)> obtained in this manner is a candidate selectional preference for *p*. Following Pantel et al. (2007), we rank these candidates using Pointwise mutual information (Cover and Thomas 1991). The ranking function is defined as the strength of association between two semantic classes, c_x and c_y[2], given the relation *p*:

$$pmi\left(c_x|p; c_y|p\right) = \log \frac{P\left(c_x, c_y|p\right)}{P\left(c_x|p\right)P\left(c_y|p\right)} \tag{3.1}$$

Let $|c_x, p, c_y|$ denote the frequency of observing the instance <*c*(*x*), *p*, *c*(*y*)>. We estimate the probabilities of Equation 3.1 using maximum likelihood estimates over our corpus:

$$P\left(c_x|p\right) = \frac{|c_x, p, *|}{|*, p, *|} \quad P\left(c_y|p\right) = \frac{|*, p, c_y|}{|*, p, *|} \tag{3.2}$$
$$P\left(c_x, c_y|p\right) = \frac{|c_x, p, c_y|}{|*, p, *|}$$

We estimate the above frequencies using:

$$|c_x, p, *| = \sum_{w \in c_x} \frac{|w, p, *|}{|C(w)|} \quad |*, p, c_y| = \sum_{w \in c_y} \frac{|*, p, w|}{|C(w)|} \tag{3.3}$$
$$|c_x, p, c_y| = \sum_{w_1 \in c_x, w_2 \in c_y} \frac{|w_1, p, w_2|}{|C(w_1)| \times |C(w_2)|}$$

where |*x*, *p*, *y*| denotes the frequency of observing the instance <*x*, *p*, *y*> and |C(*w*)| denotes the number of classes to which word *w* belongs. |C(*w*)| distributes *w*'s mass equally among all of its senses C(*w*).

Model 2: Independent Relational Model (IRM)

Due to sparse data, the JRM is likely to miss some pair(s) of valid relational selectional preferences. Hence we use the IRM, which models the arguments of a binary semantic relation independently.

Similar to JRM, we find all instances of the form <*x, p, y*> for a relation *p*. We then find the sets *C*(*x*) and *C*(*y*) of the semantic classes that *x* and *y* belong to and accumulate the frequencies of the triples <*c*(*x*), *p*, *> and <*, *p*, *c*(*y*)> where $c(x) \in C(x)$ and $c(y) \in C(y)$.

All the tuples <*c*(*x*), *p*, *> and <*, *p*, *c*(*y*)> are the independent candidate RSPs for a relation *p* and we rank them according to equation 3.3.

Once we have the independently learnt RSPs, we need to convert them into a joint representation for use by the inference plausibility and directionality model. To do this, we obtain the Cartesian product between the sets <*C*(*x*), *p*, *> and <*, *p*, *C*(*y*)> for a relation *p*. The Cartesian product between two sets A and B is given by:

$$A \times B = \left\{(a,b) : \forall a \in A \quad and \quad \forall b \in B\right\} \tag{3.4}$$

Similarly we obtain:

$$\langle C_x, p, * \rangle \times \langle *, p, C_y \rangle = \left\{ \begin{matrix} \langle c_x, p, c_y \rangle : \ \forall \langle c_x, p, * \rangle \in \langle C_x, p, * \rangle \quad and \\ \forall \langle *, p, c_y \rangle \in \langle *, p, C_y \rangle \end{matrix} \right\} \tag{3.5}$$

The Cartesian product in equation 3.5 gives the joint representation of the RSPs of the relation *p* learnt using IRM. In the joint representation, the IRM RSPs have the form <*c*(*x*), *p*, *c*(*y*)> which is the same form as the JRM RSPs.

3.3 Inference plausibility and directionality model

Our model for determining inference plausibility and directionality is based on the intuition that for an inference to hold between two semantic relations there must exist sufficient overlap between their contexts and the directionality of the inference depends on the quantitative comparison between their contexts.

Here we model the context of a relation by the selectional preferences of that relation. We determine the plausibility of an inference based on the overlap coefficient (Manning and Schütze, 1999) between the selectional preferences of the two paths. We determine the directionality based on the difference in the number of selectional preferences of the relations when the inference seems plausible.

Given a candidate inference rule $p_i \Leftrightarrow p_j$, we first obtain the RSPs <*C*(*x*), p_i, *C*(*y*)> for p_i and <*C*(*x*), p_j, *C*(*y*)> for p_j. We then calculate the overlap coefficient between their respective RSPs. Overlap coefficient is one of the many distribu-

[2] c_x and c_y are shorthand for *c*(*x*) and *c*(*y*) in our equations.

tional similarity measures used to calculate the similarity between two vectors A and B:

$$sim(A,B) = \frac{|A \cap B|}{\min(|A|,|B|)} \qquad (3.6)$$

The overlap coefficient between the selectional preferences of p_i and p_j is calculated as:

$$sim(p_i,p_j) = \frac{|\langle C_x,p_i,C_y\rangle \cap \langle C_x,p_j,C_y\rangle|}{\min(|C_x,p_i,C_y|,|C_x,p_j,C_y|)} \qquad (3.7)$$

If sim(p_i,p_j) is above a certain empirically determined threshold α (≤1), we conclude that the inference is plausible, i.e.:

```
If  $sim(p_i,p_j) \geq \alpha$
        we conclude the inference is plausible
else
        we conclude the inference is not plausible
```

For a plausible inference, we then compute the ratio between the number of selectional preferences $|C(x), p_i, C(y)|$ for p_i and $|C(x), p_j, C(y)|$ for p_j and compare it against an empirically determined threshold β (≥1) to determine the direction of inference. So the algorithm is:

```
If       $\frac{|C_x,p_i,C_y|}{|C_x,p_j,C_y|} \geq \beta$     we conclude $p_i \Leftarrow p_j$
else if  $\frac{|C_x,p_i,C_y|}{|C_x,p_j,C_y|} \leq \frac{1}{\beta}$     we conclude $p_i \Rightarrow p_j$
else                                 we conclude $p_i \Leftrightarrow p_j$
```

4 Experimental Setup

In this section, we describe our experimental setup to validate our claim that LEDIR can be used to determine plausibility and directionality of an inference rule.

Given an inference rule of the form $p_i \Leftrightarrow p_j$, we want to use automatically learned relational selectional preferences to determine whether the inference rule is valid and if it is valid then what its directionality is.

4.1 Inference Rules

LEDIR can work with any set of binary semantic inference rules. For the purpose of this paper, we chose the inference rules from the DIRT resource (Lin and Pantel 2001). DIRT consists of 12 million rules extracted from 1GB of newspaper text (AP Newswire, San Jose Mercury and Wall Street Journal). For example, "*X eats Y*" ⇔ "*X likes Y*" is an inference rule from DIRT.

4.2 Semantic Classes

Appropriate choice of semantic classes is crucial for learning relational selectional preferences. The ideal set should have semantic classes that have the right balance between abstraction and discrimination, the two important characteristics that are often conflicting. A very general class has limited discriminative power, while a very specific class has limited abstractive power. Finding the right balance here is a separate research problem of its own.

Since the ideal set of universally acceptable semantic classes in unavailable, we decided to use the Pantel et al. (2007) approach of using two sets of semantic classes. This approach gave us the advantage of being able to experiment with sets of classes that vary a lot in the way they are generated but try to maintain the granularity by obtaining approximately the same number of classes.

The first set of semantic classes was obtained by running the CBC clustering algorithm (Pantel and Lin, 2002) on TREC-9 and TREC-2002 newswire collections consisting of over 600 million words. This resulted in 1628 clusters, each representing a semantic class.

The second set of semantic classes was obtained by using WordNet 2.1 (Fellbaum 1998). We obtained a cut in the WordNet noun hierarchy[3] by manual inspection and used all the synsets below a cut point as the semantic class at that node. Our inspection showed that the synsets at depth four formed the most natural semantic classes[4]. A cut at depth four resulted in a set of 1287 semantic classes, a set that is much coarser grained than WordNet which has an average depth of 12. This seems to be a depth that gives a reasonable abstraction while maintaining good discriminative power. It would however be interesting to experiment with more sophisticated algorithms for extracting semantic classes from WordNet and see their effect

[3] Since we are dealing with only noun binary relations, we use only WordNet noun Hierarchy.

[4] By natural, here, we simply mean that a manual inspection by the authors showed that, at depth four, the resulting clusters had struck a better granularity balance than other cutoff points. We acknowledge that this is a very coarse way of extracting concepts from WordNet.

on the relational selectional preferences, something we do not address this in this paper.

4.3 Implementation

We implemented LEDIR with both the JRM and IRM models using inference rules from DIRT and semantic classes from both CBC and WordNet. We parsed the 1999 AP newswire collection consisting of 31 million words with Minipar (Lin 1993) and used this to obtain the probability statistics for the models (as described in section 3.2).

We performed both system-wide evaluations and intrinsic evaluations with different values of α and β parameters. Section 5 presents these results and our error analysis.

4.4 Gold Standard Construction

In order to evaluate the performance of the different systems, we compare their outputs against a manually annotated gold standard. To create this gold standard, we randomly sampled 160 inference rules of the form $p_i \Leftrightarrow p_j$ from DIRT. We discarded three rules since they contained nominalizations[5].

For every inference rule of the form $p_i \Leftrightarrow p_j$, the annotation guideline asked annotators (in this paper we used two annotators) to choose the most appropriate of the four options:

1. $p_i \Leftrightarrow p_j$
2. $p_i \Rightarrow p_j$
3. $p_i \Leftarrow p_j$
4. *No plausible inference*

To help the annotators with their decisions, the annotators were provided with 10 randomly chosen instances for each inference rule. These instances, extracted from DIRT, provided the annotators with context where the inference could hold. So for example, for the inference rule "*X eats Y*" ⇔ "*X likes Y*", an example instance would be "*I eat spicy food*" ⇔ "*I like spicy food*". The annotation guideline however gave the annotators the freedom to think of examples other than the ones provided to make their decisions.

The annotators found that while some decisions were quite easy to make, the more complex ones often involved the choice between bi-directionality and one of the directions. To minimize disagreements and to get a better understanding of the task, the annotators trained themselves by annotating several samples together.

We divided the set of 157 inference rules, into a development set of 57 inference rules and a blind test set of 100 inference rules. Our two annotators annotated the development test set together to train themselves. The blind test set was then annotated individually to test whether the task is well defined. We used the kappa statistic (Siegel and Castellan Jr. 1988) to calculate the inter-annotator agreement, resulting in κ=0.63. The annotators then looked at the disagreements together to build the final gold standard.

All this resulted in a final gold standard of 100 annotated DIRT rules.

4.5 Baselines

To get an objective assessment of the quality of the results obtained by using our models, we compared the output of our systems against three baselines:

B-random: *Randomly assigns one of the four possible tags to each candidate inference rule.*

B-frequent: *Assigns the most frequently occurring tag in the gold standard to each candidate inference rule.*

B-DIRT: *Assumes each inference rule is bidirectional and assigns the bidirectional tag to each candidate inference rule.*

5 Experimental Results

In this section, we provide empirical evidence to validate our claim that the plausibility and directionality of an inference rule can be determined using LEDIR.

5.1 Evaluation Criterion

We want to measure the effectiveness of LEDIR for the task of determining the validity and directionality of a set of inference rules. We follow the standard approach of reporting system accuracy by comparing system outputs on a test set with a manually created gold standard. Using the gold standard described in Section 4.4, we measure the accuracy of our systems using the following formula:

[5] For the purpose of simplicity, we in our experiments did not use DIRT rules containing nominalizations. The algorithm however can be applied without change to inference rules containing nominalization. In fact, in the resource that we plan to release soon, we have applied the algorithm without change to DIRT rules containing nominalizations.

$$Accuracy = \frac{|correctly \quad tagged \quad \inf erences|}{|input \quad \inf erences|}$$

5.2 Result Summary

We ran all our algorithms with different parameter combinations on the development set (the 57 DIRT rules described in Section 4.4). This resulted in a total of 420 experiments on the development set. Based on these experiments, we used the accuracy statistic to obtain the best parameter combination for each of our four systems. We then used these parameter values to obtain the corresponding percentage accuracies on the test set for each of the four systems.

Model		α	β	Accuracy (%)
B-random		-	-	25
B-frequent		-	-	34
B-DIRT		-	-	25
JRM	CBC	0.15	2	38
	WN	0.55	2	38
IRM	**CBC**	**0.15**	**3**	**48**
	WN	0.45	2	43

Table 1: Summary of results on the test set

Table 1 summarizes the results obtained on the test set for the three baselines and for each of the four systems using the best parameter combinations obtained as described above. The overall best performing system uses the IRM algorithm with RSPs form CBC. Its performance is found to be significantly better than all the three baselines using the Student's paired t-test (Manning and Schütze, 1999) at $p<0.05$. However, this system is not statistically significant when compared with the other LEDIR implementations (JRM and IRM with WordNet).

5.3 Performance and Error Analysis

The best performing system selected using the development set is the IRM system using CBC with the parameters α=0.15 and β=3. In general, the results obtained on the test set show that the IRM tends to perform better than the JRM. This observation points at the sparseness of data available for learning RSPs for the more restrictive JRM, the reason why we introduced the IRM in the first place. A much larger corpus would be needed to obtain good enough coverage for the JRM.

		GOLD STANDARD			
		⇔	⇒	⇐	NO
SYSTEM	⇔	16	1	3	7
	⇒	0	3	1	3
	⇐	7	4	22	15
	NO	2	3	4	9

Table 2: Confusion Matrix for the best performing system, IRM using CBC with α=0.15 and β=3.

Table 2 shows the confusion matrix for the overall best performing system as selected using the development set (results are taken from the test set). The confusion matrix indicates that the system does a very good job of identifying the directionality of the correct inference rules, but gets a big performance hit from its inability to identify the incorrect inference rules accurately. We will analyze this observation in more detail below.

Figure 1 plots the variation in accuracy of IRM with different RSPs and different values of α and β. The figure shows a very interesting trend. It is clear that for all values of β, systems for IRM using CBC tend to reach their peak in the range 0.15 ≤ α ≤ 0.25, whereas the systems for IRM using WordNet (WN), tend to reach their peak in the range 0.4 ≤ α ≤ 0.6. This variation indicates the kind of impact the selection of semantic classes could have on the overall performance of the system. This is not hard evidence, but it does suggest that finding the right set of semantic classes could be one big step towards improving system accuracy.

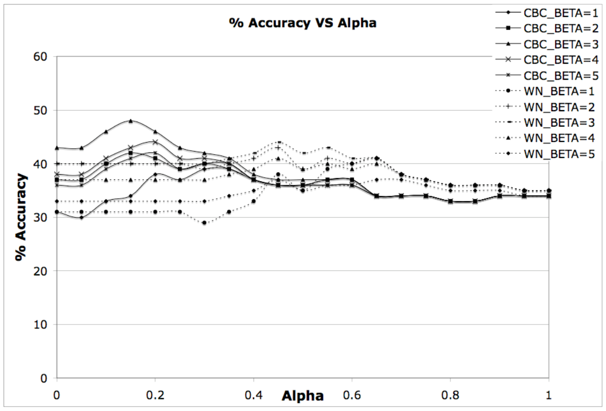

Figure 1: Accuracy variation for IRM with different values of α and β.

Two other factors that have a big impact on the performance of our systems are the values of the system parameters α and β, which decide the plausibility and directionality of an inference rule, respectively. To better study their effect on the system performances, we studied the two parameters independently.

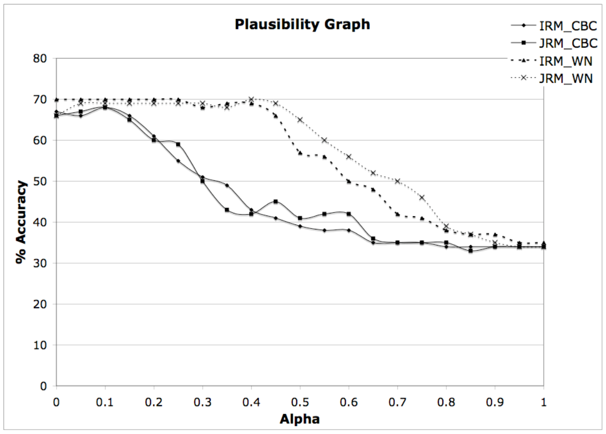

Figure 2: Accuracy variation in predicting correct versus incorrect inference rules for different values of α.

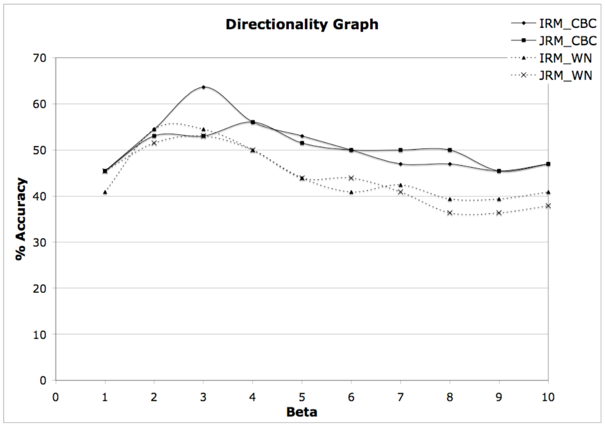

Figure 3: Accuracy variation in predicting directionality of correct inference rules for different values of β.

Figure 2 shows the variation in the accuracy for the task of predicting the correct and incorrect inference rules for the different systems when varying the value of α. To obtain this graph, we classified the inference rules in the test set only as correct and incorrect without further classification based on directionality. All of our four systems obtained accuracy scores in the range of 68-70% showing a good performance on the task of determining plausibility. This however is only a small improvement over the baseline score of 66% obtained by assuming every inference to be plausible (as will be shown below, our system has most impact not on determining plausibility but on determining directionality). Manual inspection of some system errors showed that the most common errors were due to the well-known 'problem of antonymy' when applying the distributional hypothesis. In DIRT, one can learn rules like "*X loves Y*" ⇔ "*X hates Y*". Since the plausibility of inference rules is determined by applying the distributional hypothesis and the antonym paths tend to take the same set of classes for X and Y, our models find it difficult to filter out the incorrect inference rules which DIRT ends up learning for this very same reason. To improve our system, one avenue of research is to focus specifically on filtering incorrect inference rules involving antonyms (perhaps using methods similar to (Lin et al. 2003)).

Figure 3 shows the variation in the accuracy for the task of predicting the directionality of the correct inference rules for the different systems when varying the value of β. To obtain this graph, we separated the correct inference rules form the incorrect ones and ran all the systems on only the correct ones, predicting only the directionality of each rule for different values of β. Too low a value of β means that the algorithms tend to predict most things as unidirectional and too high a value means that the algorithms tend to predict everything as bidirectional. It is clear from the figure that the performance of all the systems reach their peak performance in the range 2 ≤ β ≤ 4, which agrees with our intuition of obtaining the best system accuracy in a medium range. It is also seen that the best accuracy for each of the models goes up as compared to the corresponding values obtained in the general framework. The best performing system, IRM using CBC RSPs, reaches a peak accuracy of 63.64%, a much higher score than its accuracy score of 48% under the general framework and also a significant improvement over the baseline score of 48.48% for this task. Paired t-test shows that the difference is statistically significant at $p<0.05$. The baseline score for this task is obtained by assigning the most frequently occurring direction to all the correct inference rules. This paints a very encouraging picture about the ability of the algorithm to identify the directionality much more accurately if it can be provided with a cleaner set of inference rules.

6 Conclusion

Semantic inferences are fundamental to understanding natural language and are an integral part of many natural language applications such as question answering, summarization and textual entailment. Given the availability of large amounts of text and with the increase in computation power, learning them automatically from large text corpora has become increasingly feasible and popular. We introduced the Directionality Hypothesis, which states that if two paths share a significant number of relational selectional preferences (RSPs) and if the first has many more RSPs than the second, then the second path implies the first. Our experiments show empirical evidence that the Directionality Hypothesis with RSPs can indeed be used to filter incorrect inference rules and find the directionality of correct ones. We believe that this result is one step in the direction of solving the basic problem of semantic inference.

Several questions must still be addressed. The models need to be improved in order to address the problem of incorrect inference rules. The distributional hypothesis does not provide a framework to address the issue with antonymy relations like "*X loves Y*" ⇔ "*X hates Y*" and hence other ideas need to be investigated.

Ultimately, our goal is to improve the performance of NLP applications with better inferencing capabilities. Several recent data points, such as (Harabagiu and Hickl 2006), and others discussed in Section 2.1, give promise that refined inference rules for directionality may indeed improve question answering, textual entailment and multi-document summarization accuracies. It is our hope that methods such as the one proposed in this paper may one day be used to harness the richness of automatically created inference rule resources within large-scale NLP applications.

Abstract

This paper assesses the role of multi-label classification in modelling polysemy for language acquisition tasks. We focus on the acquisition of semantic classes for Catalan adjectives, and show that polysemy acquisition naturally suits architectures used for multi-label classification. Furthermore, we explore the performance of information drawn from different levels of linguistic description, using feature sets based on morphology, syntax, semantics, and n-gram distribution. Finally, we demonstrate that ensemble classifiers are a powerful and adequate way to combine different types of linguistic evidence: a simple, majority voting ensemble classifier improves the accuracy from 62.5% (best single classifier) to 84%.

1 Introduction

This paper reports on a series of experiments to explore the automatic acquisition of semantic classes for Catalan adjectives. The most important challenge of the classification task is to model the assignment of polysemous lexical instances to multiple semantic classes, combining a) a state-of-the-art Machine Learning architecture for *Multi-label Classification* (Schapire and Singer, 2000; Ghamrawi and McCallum, 2005) and an *Ensemble Classifier* (Dietterich, 2002) with b) the definition of features at various levels of linguistic description.

A proper treatment of polysemy is essential in the area of lexical acquisition, since polysemy represents a pervasive phenomenon in natural language. However, previous approaches to the automatic acquisition of semantic classes have mostly disregarded the problem (cf. Merlo and Stevenson, 2001 and Stevenson and Joanis, 2003 for English semantic verb classes, or Schulte im Walde, 2006 for German semantic verb classes). There are a few exceptions to this tradition, such as Pereira et al. (1993), Rooth et al. (1999), Korhonen et al. (2003), who used soft clustering methods for multiple assignment to verb semantic classes.

Our work addresses the lack of methodology in modelling a polysemous classification. We implement a multi-label classification architecture to handle polysemy. This paper concentrates on the classification of Catalan adjectives, but the general nature of the architecture should allow related tasks to profit from our insights.

As target classification for the experiments, a set of 210 Catalan adjectives was manually classified by experts into three simple and three polysemous semantic classes. We deliberately decided in favour of a small-scale, broad classification. So far, there is little work on the semantic classification of adjectives, as opposed to verbal semantic classification. The semantic classification we propose is a first step in characterising adjectival meaning, and can be refined and extended in subsequent work.

The experiments also provide a thorough comparison of feature sets based on different levels of linguistic description (morphology, syntax, semantics). A set of features is defined for each level of description, and its performance is assessed within the series of experiments. An ensemble classifier comple-

Proceedings of the 2007 Joint Conference on Empirical Methods in Natural Language Processing and Computational Natural Language Learning, pp. 171–180, Prague, June 2007. ©2007 Association for Computational Linguistics

ments the classification architecture, by optimising the combination of these different types of linguistic evidence.

Our task is motivated by the fact that adjectives play an important role in sentential semantics: they are crucial in determining the reference of NPs, and in defining properties of entities. Even using only three different classes, the information acquired could be applied to, e.g., identify referents in a given context in Dialog or Question Answering systems, and to induce properties of objects within Information Extraction tasks. Furthermore, with the semantic classes corresponding to broad sense representations, they can be exploited for Word Sense Disambiguation.

The remainder of this paper is organised as follows. Section 2 provides background on Catalan adjectives, and Section 3 presents the Gold Standard classification. Section 4 introduces the methodology of the multi-label classification experiments, Section 5 discusses the results, and the improved ensemble classifier is presented in Section 6.

2 Catalan adjective classes

The definition and characterisation of our target semantic classification follows the proposal by Raskin and Nirenburg (1998) within the framework of Ontological Semantics(Nirenburg and Raskin, 2004). In Ontological Semantics, an ontology of concepts modelling the world is explicitly defined, and the semantics of words are mapped onto elements of the ontology. The classification pursued in this paper is drawn up based on the ontological sort of adjectival denotation: all adjectives denote properties, but these properties can be instantiated as simple attributes (*basic adjectives*), relationships to objects (*object-related adjectives*), or relationships to events (*event-related adjectives*).

Basic adjectives are the prototypical adjectives which denote attributes or properties and cannot be decomposed further (such as *bonic* 'beautiful', *gran* 'big'). In Ontological Semantics, these adjectives are mapped to concepts of type *attribute*. For instance, the semantics of the adjective *gran* specifies a mapping to the *size-attribute* element in the ontology. As for event-related adjectives, they have an event component in their meaning and are therefore mapped onto *event* concepts in the ontology. For instance, the semantics of *tangible* ('tangible') includes a pointer to the event element *touch* in the ontology. Similarly, object-related adjectives are mapped onto object concepts in the ontology: *deformació nasal* ('nasal deformity') can be paraphrased as *deformity that affects the nose*, so *nasal* evokes the object *nose*.

The semantic distinctions are mirrored at several levels of linguistic description, such as morphology, syntax, and semantics. For instance, there is a clear relationship between morphological type and semantic class: basic adjectives are typically non-derived, object adjectives tend to be denominal, and event adjectives are usually deverbal. This is the default mapping that one expects from the morphology-semantics interface. As an example for syntactic evidence, basic adjectives in Catalan can be used non-restrictively (in a pre-nominal position) and also predicatively, while object adjectives typically cannot.

However, the correspondences between the linguistic properties and the semantic classes are not one-to-one mappings. Taking the morphological level as an example, some denominal adjectives are basic (such as *vergonyós* 'shy', from *vergonya* 'shyness'). Conversely, some object adjectives are not synchronically denominal (such as *botànic* 'botanical'), and some deverbal adjectives are not event-related, such as *amable* (lit. 'suitable to be loved'; has evolved to 'kind, friendly'). In such cases, the semantic class can be better traced in the distributional properties, not the morphological properties of the adjective.

The proposed classification accounts for some cases of adjectival polysemy. For instance, *familiar* has an object reading (related to the Catalan noun for 'family'), and a basic reading (corresponding to the English adjective 'familiar'):

(1) reunió familiar / cara familiar
meeting familiar / face familiar

'family meeting / familiar face'

Similarly, the participial adjective *sabut* ('known') has an event-related sense, corresponding to the verb *saber* ('know'), and a basic sense equivalent to 'wise':

(2) conseqüència sabuda / home sabut
consequence known / man wise
'known consequence / wise man'

The polysemy between our proposed classes, as exemplified in (1) and (2), is the kind of polysemy we aim to model in the acquisition experiments reported in this paper.

3 Gold Standard classes

As a Gold Standard for the experiments to follow, 210 Catalan adjectives were classified by three experts. The adjectives were randomly sampled from an adjective database (Sanromà, 2003), balancing three factors of variability: frequency, morphological type, and suffix. An equal number of adjectives was chosen from three frequency bands (low, medium, high), from four derivational types (denominal, deverbal, non-derived, participle), and from a series of suffixes within each type. The derivational type and suffix of each adjective were available in the adjective database, and had been manually encoded.

Three experts assigned the 210 lemmata to one out of six classes: each adjective was tagged as basic (B), event (E), object (O), or as polysemous between basic and event (BE), between basic and object (BO), or between event and object (EO). The decisions were reached by consensus. The distribution of the Gold Standard material across classes is shown in the last column of Table 6 (Section 5.2).

In the acquisition experiments, our aim is to automatically assign a class to each adjective that can be simple (B, E, O) or complex (BE, BO, EO), in case of polysemy.

4 Classification method

Adjective classification was performed within a two-level architecture for multi-label classification: first, make a binary decision on each of the classes, and then combine the classifications to achieve a final, multi-label classification. We therefore decomposed the global decision on the (possibly polysemous) class of an adjective into three binary decisions: Is it basic or not? Is it event-related or not? Is it object-related or not? The individual decisions were then combined into an overall classification that included polysemy. For example, if a lemma was classified both as basic and as object in each of the binary decisions, it was deemed polysemous (BO). The motivation behind this approach was that polysemous adjectives should exhibit properties of all the classes involved. As a result, positive decisions on each binary classification can be made by the algorithm, which can be viewed as implicit polysemous assignments.

This classification architecture is very popular in Machine Learning for multi-label problems, cf. (Schapire and Singer, 2000; Ghamrawi and McCallum, 2005), and has also been applied to NLP problems such as entity extraction and noun-phrase chunking (McDonald et al., 2005). The remainder of this section describes other methodological aspects of our experiments.

4.1 Classifier: Decision Trees

As classifier for the binary decisions we chose Decision Trees, one of the most widely used Machine Learning techniques for supervised experiments (Witten and Frank, 2005). Decision Trees provide a transparent representation of the decisions made by the algorithm, and thus facilitate the inspection of results and the error analysis. The experiments were carried out with the freely available Weka software package. The particular algorithm chosen, Weka's J48, is the latest open source version of C4.5 (Quinlan, 1993). For an explanation of decision tree induction and C4.5, see Quinlan (1993) and Witten and Frank (2005, Sections 4.3 and 6.1).

4.2 Feature definition

Five levels of linguistic description, formalised as different feature sets, were chosen for our task. They included evidence from morphology (*morph*), syntax (*func*, *uni*, *bi*), semantics (*sem*), plus a combination of the five levels (*all*). Table 1 lists the linguistic levels, their explanations, and the number of features used on each level.[1] Morphological features (*morph*) encode the derivational type (denominal, deverbal, participial, non-derived) and the suffix (in case the adjective is derived) of each adjective, and correspond to the manually encoded informa-

[1] In level *all*, different features were used for each of the three classes. Table 1 reports the mean number of features across the three classes.

Level	Explanation	# Features
morph	morphological (derivational) properties	2
func	syntactic function	4
uni	uni-gram distribution	24
bi	bi-gram distribution	50
sem	distributional cues of semantic properties	18
all	combination of the 5 linguistic levels	10.3

Table 1: Linguistic levels as feature sets.

tion from the adjective database. Syntactic and semantic features encode distributional properties of adjectives. Syntactic features comprise three subtypes: (i) the syntactic function (level *func*) of the adjective, as assigned by a shallow Constraint Grammar (Alsina et al., 2002), distinguishing the modifier (pre-nominal or post-nominal) and predicative functions; (ii) a unigram distribution (level *uni*), independently encoding the parts of speech (POS) of the words preceding and following the adjective, respectively; and (iii) a bigram distribution (level *bi*), the POS bigram around the target adjective, considering only the 50 most frequent bigrams to avoid sparse features. Semantic features (level *sem*) expand syntactic features with heterogeneous shallow cues of semantic properties. Table 2 lists the semantic properties encoded in the features, as well as the number of heuristic cues defined for each property. As an example, one of the shallow cues used for gradability was the presence of degree adverbs (*més* ‘more’, *menys* ‘less’) to the left of the target adjectives. The last set of features, *all*, combines features from all levels of description. However, it does not contain all features, but a selection of the most relevant ones (further details in Section 4.3).

property	#
non-restrictivity	1
predicativity	4
gradability	4
syntactic function of head noun	3
distance to the head noun	1
binaryhood (adjectives with two arguments)	1
agreement properties	2

Table 2: Semantic features.

4.3 Feature selection

Irrelevant features typically decrease performance by 5 to 10% when using Decision Trees (Witten and Frank, 2005, p. 288). We therefore applied a feature selection algorithm. We chose a feature selection method available in Weka (*WrapperSubsetEval*) that selects a subset of the features according to its performance within the Machine Learning algorithm used for classification. Accuracy for a given subset of features is estimated by cross-validation over the training data. Because the number of subsets increases exponentially with the number of features, this method is computationally very expensive, and we used a best-first search strategy to alleviate this problem.

We additionally used the feature selection procedure to select the features for level *all*: for each class, we used only those features that were selected by the feature selection algorithm in at least 30% of the experiments.

4.4 Differences across linguistic levels

One of our goals was to test the strengths and weaknesses of each level of linguistic description for the task of adjective classification. This was done by comparing the accuracy results obtained with each of the feature sets in the Machine Learning experiments. Following a standard procedure in Machine Learning, we created several partitions of the data to obtain different estimates of the accuracy of each of the levels, so as to be able to perform a significance test on the differences in accuracy. We performed 10 experiments with 10-fold cross-validation (*10x10 cv* for short), so that for each class 100 different binary decisions were made for each adjective. For the comparison of accuracies, a standard paired t-test could not be used, because of the inflated Type I error probability when reusing data (Dietterich, 1998). Instead, we used the *corrected resampled t-test* as proposed by Nadeau and Bengio (2003).[2]

5 Classification results

5.1 Accuracy results

The accuracy results for each of the binary decisions (basic/non-basic, event/non-event, object/non-object) are depicted in Table 3.[3] Level *bl* corresponds to the baseline: the baseline accuracy was determined by assigning all lemmata to the most frequent class. The remaining levels follow the nomenclature in Table 1 above. Each column contains the mean and the standard deviation (marked by ±) of the accuracy for the relevant level of information over the 100 results obtained with 10x10 cv.

	Basic	**Event**	**Object**
bl	65.2 ±11.1	76.2 ±9.9	71.9 ±9.6
morph	72.5 ±7.9	89.1 ±6.0	84.2 ±7.5
func	73.6 ±9.3	76.0 ±9.3	81.7 ±7.4
uni	66.1 ±9.4	75.1 ±10.6	82.2 ±7.5
bi	67.4 ±10.6	72.3 ±10.2	83.0 ±8.3
sem	72.8 ±9.0	73.8 ±9.6	82.3 ±8.0
all	**75.3** ±7.6	**89.4** ±5.7	**85.4** ±8.7

Table 3: Accuracy results for binary decisions.

As one might have expected, the best results were obtained with the *all* level (bold faced in Table 3), which is the combination of all feature types. This level achieved a mean improvement of 12.3% over the baseline. The differences in accuracy results between most levels of information were, however, rather small. For the object class, all levels except for *func* and *uni* achieved a significant improvement over the baseline. For the basic class, no improvement over the baseline was significant according to the corrected resampled t-test. And for the event class, only levels *morph* and *all* offered a significant improvement in accuracy; the remaining levels even obtained a slightly lower accuracy score.

These results concern the three individual binary decisions. However, our goal was not to obtain three separate decisions, but a single classification including polysemy. Table 4 shows the accuracy results for the classification obtained by combining the three individual decisions for each adjective. We report two accuracy measures, full and partial: full accuracy required the class assignments to be identical; partial accuracy only required some overlap in the classification of the Machine Learning algorithm and the Gold Standard for a given class assignment. The motivation for calculating partial overlap was that a class assignment with some overlap with the Gold Standard (even if they were not identical) is generally more useful than a class assignment with no overlap.

	Full	**Partial**
bl	51.0 ±0.0	65.2 ±0.0
morph	60.6 ±1.3	87.8 ±0.4
func	53.5 ±1.8	79.8 ±1.3
uni	52.3 ±1.7	76.7 ±1.0
bi	52.9 ±1.9	76.9 ±1.8
sem	52.0 ±1.3	78.7 ±1.7
all	**62.3** ±2.3	**90.7** ±1.6

Table 4: Accuracy results for combined decisions.

Again, the best results were obtained with the *all* level. The second best results were obtained with level *morph*. These results could have been expected from the results obtained by the individual decisions (Table 3); however, note that the differences between the various levels are much clearer in the combined classification than in the individual binary decisions.

Table 5 shows the two-by-two comparisons of the accuracy scores. Each cell contains the difference in accuracy means between two levels of description, as well as the level of significance of the difference. The significance is marked as follows: * for $p < 0.05$, ** for $p < 0.01$, *** for $p < 0.001$. If no asterisk is shown, the difference was not significant.

Under the strictest evaluation condition (full accu-

[2] Note that the corrected resampled t-test can only compare accuracies obtained under two conditions (algorithms or, as is our case, feature sets); ANOVA would be more adequate. In the field of Machine Learning, there is no established correction for ANOVA for the purposes of testing differences in accuracy (Bouckaert, 2004). Therefore, we used multiple t-tests instead, which increases the overall error probability of the results for the significance tests.

[3] The accuracy for each decision was computed independently. For instance, a *BE* adjective was judged correct within the basic class iff the decision was *basic*; correct within the event class iff the decision was *event*; and correct within the object class iff the decision was *non-object*.

agreement	level	bl	morph	func	uni	bi	sem
full	morph	9.7***					
	func	2.5*	-7.1***				
	uni	1.4	-8.3***	-1.1			
	bi	2.0	-7.7***	-0.6	0.6		
	sem	1.0	-8.7***	-1.5	-0.4	1.0	
	all	11.4***	1.7	8.9***	10.0***	9.4***	10.4***
partial	morph	-22.6***					
	func	14.6***	-8.0***				
	uni	11.4***	-11.1***	-3.1**			
	bi	11.7***	-10.9***	-2.9**	0.2		
	sem	13.4***	-9.1***	-1.1	2.0	1.8	
	all	25.4***	2.9*	10.9***	14.0***	13.8***	12.0***

Table 5: Comparison of accuracy scores across linguistic levels.

racy), only levels *morph*, *func*, and *all* significantly improved upon the baseline. Levels *morph* and *all* are better than the remaining levels, to a similar extent. In the partial evaluation condition, all levels achieved a highly significant improvement over the baseline ($p < 0.001$). Therefore, the classifications obtained with any of the feature levels are more useful than the baseline, in the sense that they present more overlap with the Gold Standard.

The best result obtained for the full classification of adjectives with our methodology achieved a mean of 62.3% (full accuracy) or 90.7% (partial accuracy), which represents an improvement of 11.3% and 25.5% over the baselines, respectively. Levels including morphological information were clearly superior to levels using only distributional information.

These results suggest that morphology is the best single source of evidence for our task. However, recall from Section 3 that the sampling procedure for the Gold Standard explicitly balanced for morphological factors. As a result, denominal and participial adjectives are underrepresented in the Gold Standard, while non-derived and deverbal adjectives are overrepresented. Moreover, previous experiments on different datasets (Boleda et al., 2004; Boleda et al., 2005) provided some evidence that distributional information outperforms morphological information for our task. Therefore, we cannot conclude from the experiments that morphological features are the most important information for the classification of Catalan adjectives in general.

5.2 Error analysis

The error analysis focuses on the two best feature sets, *morph* and *all*. Table 6 compares the errors made by the experiment classifications (based on the two sets of features) against the Gold Standard classification. To obtain a unique experiment classification for each feature level in this comparison, we applied majority voting across the 10 different classifications obtained in the 10 experiment runs for each of the linguistic levels. The table rows correspond to the Gold Standard classification and the columns correspond to the experiment classifications with the feature levels *all* and *morph*, respectively. The matches (the diagonal elements) are in italics, and off-diagonal cells representing the largest numbers of mismatches are boldfaced. The overall number of mistakes made by both levels with majority voting is almost the same: 86 (*morph*) vs. 89 (*all*). However, the mismatches are qualitatively quite different.

Level *morph* uniformly mapped denominal adjectives to both basic and object (BO). Because of this overgeneration of BOs, 31 lemmata that were tagged as either basic or object in the Gold Standard were assigned to BO. In contrast, level *all* was overly discriminative: most of the BO cases (16 out of 23), as well as 16 object adjectives, were assigned to basic. This type of confusion could be explained by the fact that some non-prototypical basic adjectives were as-

		all						**morph**						
		B	BE	BO	E	EO	O	B	BE	BO	E	EO	O	*Total*
GS	B	*94*	**12**	0	0	1	0	*82*	2	**10**	**11**	2	0	*107*
	BE	1	*6*	0	0	0	0	0	*1*	0	6	0	0	*7*
	BO	**16**	1	*5*	1	0	0	5	0	*16*	2	0	0	*23*
	E	5	**23**	1	*7*	1	0	4	7	0	*25*	1	0	*37*
	EO	0	2	0	0	*4*	0	0	0	0	6	*0*	0	*6*
	O	**16**	1	6	2	0	*5*	6	0	**21**	3	0	*0*	*30*
	Total	*132*	*45*	*12*	*10*	*6*	*5*	*97*	*10*	*47*	*53*	*3*	*0*	*210*

Table 6: Levels *all* and *morph* against the Gold Standard.

signed to the basic class in the Gold Standard, because they did not fit the narrower definitions of the event and object classes, but these adjectives do not behave like typical basic adjectives.

As for event adjectives, the *morph* level assigned almost all deverbal adjectives to the event class, which worked well in most cases (26). However, this mapping cannot distinguish deverbal adjectives with a basic meaning (11 basic and 6 BE adjectives in the Gold Standard). Level *all*, including morphological and distributional cues, also shows difficulties with the event class, but of a different nature. Feature examination showed that the distributional differences between basic and event adjectives are not robust. For instance, according to t-tests performed on the Gold Standard (α = 0.05), only three of the 18 semantic features exhibit significant mean differences for classes basic and event. In contrast, ANOVA across the 6 classes (α = 0.05) yields significant differences for 16 out of the 18 features, which indicates that most features serve to distinguish object adjectives from basic and event adjectives. As a result of the lack of robust distributional differences between basic and event adjectives, 35 basic or event adjectives were classified as BE when using the *all* level as feature set.

Further 23 event adjectives were incorrectly classified as BE by the *all* level, but correctly classified by the *morph* level, because they are deverbal adjectives. These cases involved adjectives derived from stative verbs, such as *abundant* ('abundant') or *preferible* ('preferable'). Feature analysis revealed that deverbal adjectives derived from stative verbs are more similar to basic adjectives than those derived from process-denoting verbs.

To sum up, the default morphological mapping mentioned in Section 2 works well in most cases but has a clear ceiling, as it cannot account for deviations from the expected mapping. Distributional cues are more sensitive to these deviations, but fail mostly in the distinction between basic and event, because the differences in syntactic distribution between these classes are not robust.

6 An improved classifier

The error analysis in the previous section has shown that, although the number of mistakes made with level *morph* and *all* is comparable, the kinds of mistakes are qualitatively very different. This suggests that mixing features for the construction of a single Decision Tree, as is done in level *all*, is not the optimal way to combine the strengths of each level of description. An alternative combination can be achieved with an *ensemble classifier*, a type of classifier that has received much attention in the Machine Learning community in the last decade (Dietterich, 2002). When building an ensemble classifier, several class proposals for each item are obtained, and one of them is chosen on the basis of majority voting, weighted voting, or more sophisticated decision methods. It has been shown that in most cases, the accuracy of the ensemble classifier is higher than the best individual classifier (Freund and Schapire, 1996; Dietterich, 2000; Breiman, 2001). Within NLP, ensemble classifiers have been applied, for instance, to genus term disambiguation in machine-readable dictionaries (Rigau et al., 1997), using a majority voting scheme upon several heuristics, and to part of speech tagging, by combining the class predictions of different algorithms (van Halteren et

Levels	Full Ac.	Part. Ac.

func+uni+bi+sem	81.5 ±0.04	95.9 ±0.01
morph+func+sem+all	72.4 ±0.03	89.3 ±0.02
bl	51.0 ±0.0	65.2 ±0.0
all	62.3 ±2.3	90.7 ±1.6

Table 7: Results for ensemble classifier.

al., 1998). The main reason for the general success of ensemble classifiers is that they gloss over the biases introduced by the individual systems.

We implemented an ensemble classifier by using the different levels of description as different subsets of features, and applying majority voting across the class proposals from each level. Intuitively, this architecture is analogous to having a team of linguists and NLP engineers, each contributing their knowledge on morphology, n-gram distribution, syntactic properties, etc., and have them reach a consensus classification. We thus established a different classification for each of the 10 cross-validation runs by assigning each adjective to the class that received most votes. To enable a majority vote, at least three levels have to be combined. Table 7 contains a representative selection of the combinations, together with their accuracies. Also, the accuracies obtained with the baseline (*bl*) and the best single level (*all*) are included for comparison.

In any of the combinations tested, accuracy improved over 10% with respect to the *all* level. The best result, a mean of 84% (full accuracy), was obtained by combining all levels of description. These results represent a raw improvement over the baseline of 33%, and 21.7% over the best single classifier. Also note that with this procedure 95.7% of the classifications obtained with the ensemble classifier present partial overlap with the class assignments in the Gold Standard.

These results show that the combination of different sources of linguistic evidence is more important than the type of information used. As an example, consider the second ensemble classifier in Table 7: this classifier excludes the two levels that contain morphological information (*morph* and *all*), which represents the most successful individual source of information for our dataset. Nevertheless, the combination achieved 19.2/20.9% more accuracy than levels *all* and *morph*, respectively.

7 Related work

Adjectives have received less attention than verbs and nouns within Lexical Acquisition. Work by Hatzivassiloglou and colleagues (Hatzivassiloglou and McKeown, 1993; Hatzivassiloglou and McKeown, 1997; Hatzivassiloglou and Wiebe, 2000) used clustering methods to automatically identify adjectival scales from corpora.

Coordination information was used in Bohnet et al. (2002) for a classification task similar to the task we pursue, using a bootstrapping approach. The authors, however, pursued a classification that is not purely semantic, between quantitative adjectives (similar to determiners, like *viele* 'many'), referential adjectives (*heutige*, 'of today'), qualitative adjectives (equivalent to basic adjectives), classificatory adjectives (equivalent to object adjectives), and adjectives of origin (*Stuttgarter*, 'from Stuttgart').

In a recent paper, Yallop et al. (2005) reported experiments on the acquisition of syntactic subcategorisation patterns for English adjectives.

Apart from the above research with a classificatory flavour, other lines of research exploited lexical relations among adjectives for Word Sense Disambiguation (Justeson and Katz, 1995; Chao and Dyer, 2000). Work by Lapata (2001), contrary to the studies mentioned so far, focused on the meaning of adjective-noun combinations, not on that of adjectives alone.

8 Conclusion

This paper has presented an architecture for the semantic classification of Catalan adjectives that explicitly includes polysemous classes. The focus of the architecture was on two issues: *(i) finding an appropriate set of linguistic features,* and *(ii) defining an adequate architecture for the task.* The investigation and comparison of features at various linguistic levels has shown that morphology plays a major role for the target classification, despite the caveats raised in the discussion. Morphological features related to derivational processes are among the simplest types of features to extract, so that the approach can be straightforwardly extended to languages similar to Catalan with no extensive need of resources.

Furthermore, we have argued that polysemy acquisition naturally suits multi-label classification architectures. We have implemented a standard architecture for this class of problems, and demonstrated its applicability and success. The general nature of the architecture should be useful for related tasks that involve polysemy within the area of automatic lexical acquisition.

Our work has focused on a broad classification of the adjectives, similarly to Merlo and Stevenson (2001), who classified transitive English verbs into three semantic classes. The small number of classes might be considered as an over-simplification of adjective semantics, but the simplified setup facilitates a detailed qualitative evaluation. In addition, as there has been virtually no work on the acquisition of semantic classes for adjectives, it seems sensible to start with a small number of classes and incrementally build upon that. Previous work has demonstrated that multi-label classification is applicable also to a large number of classes as used in, e.g., document categorisation (Schapire and Singer, 2000). This potential can be exploited in future work, addressing a finer-grained adjective classification.

Finally, we have demonstrated that the combination of different types of linguistic evidence boosts the performance of the system beyond the best single type of information: ensemble classifiers are a more adequate way to combine the linguistic levels of description than simply merging all features for tree construction. Using a simple, majority voting ensemble classifier, the accuracy jumped from 62.5% (best single classifier) to 84%. This result is impressive by itself, and also in comparison to similar work such as (Rigau et al., 1997), who achieved a 9% improvement on a similar task. Our insights are therefore useful in related work which involves the selection of linguistic features in Machine Learning experiments.

Future work involves three main lines of research. First, the refinement of the classification itself, based on the results of the experiments presented. Second, the use of additional linguistic evidence that contributes to the semantic class distinctions (e.g., selectional restrictions). Third, the application of the acquired information to broader NLP tasks. For example, given that each semantic class exhibits a particular syntactic behaviour, information on the semantic class should improve POS-tagging for adjective-noun and adjective-participle ambiguities, probably the most difficult distinctions both for humans and computers (Marcus et al., 1993; Brants, 2000). Also, semantic classes might be useful in terminology extraction, where, presumably, object adjectives participate in terms more often than basic adjectives.[4]

Acknowledgements

We thank Roser Sanromà for providing us with the manually annotated database of adjectives, and for being part of the Gold Standard annotation committee. Special thanks also to the Institut d'Estudis Catalans for proding us with the research corpus. The comments of three anonymous reviewers helped improve the paper. Finally, the financial support of the Universitat Pompeu Fabra and its Translation and Philology Department and the Fundación Caja Madrid is gratefully acknowledged.

Abstract

Traditional research on spelling correction in natural language processing and information retrieval literature mostly relies on pre-defined lexicons to detect spelling errors. But this method does not work well for web query spelling correction, because there is no lexicon that can cover the vast amount of terms occurring across the web. Recent work showed that using search query logs helps to solve this problem to some extent. However, such approaches cannot deal with rarely-used query terms well due to the data sparseness problem. In this paper, a novel method is proposed for use of web search results to improve the existing query spelling correction models solely based on query logs by leveraging the rich information on the web related to the query and its top-ranked candidate. Experiments are performed based on real-world queries randomly sampled from search engine's daily logs, and the results show that our new method can achieve 16.9% relative *F*-measure improvement and 35.4% overall error rate reduction in comparison with the baseline method.

1 Introduction

Nowadays more and more people are using Internet search engine to locate information on the web. Search engines take text queries that users type as input, and present users with information of ranked web pages related to users' queries. During this process, one of the important factors that lead to poor search results is misspelled query terms. Actually misspelled queries are rather commonly observed in query logs, as shown in previous investigations into the search engine's log data that around 10%~15% queries were misspelled (Cucerzan and Brill, 2004).

Sometimes misspellings are due to simple typographic errors such as *teh* for *the*. In many cases the spelling errors are more complicated cognitive errors such as *camoflauge* for *camouflage*. As a matter of fact, correct spelling is not always an easy task – even many Americans cannot exactly spell out California governor's last name: *Schwarzenegger*. A spelling correction tool can help improve users' efficiency in the first case, but it is more useful in the latter since the users cannot figure out the correct spelling by themselves.

There has been a long history of general-purpose spelling correction research in natural language processing and information retrieval literature (Kukich, 1992), but its application to web search

Proceedings of the 2007 Joint Conference on Empirical Methods in Natural Language Processing and Computational Natural Language Learning, pp. 181–189, Prague, June 2007.

query is still a new challenge. Although there are some similarities in correction candidate generation and selection, these two settings are quite different in one fundamental problem: How to determine the validity of a search term. Traditionally, the measure is mostly based on a pre-defined spelling lexicon – all character strings that cannot be found in the lexicon are judged to be invalid. However, in the web search context, there is little hope that we can construct such a lexicon with ideal coverage of web search terms. For example, even manually collecting a full list of car names and company names will be a formidable task.

To obtain more accurate understanding of this problem, we performed a detailed investigation over one week's MSN daily query logs, among which found that 16.5% of search terms are out of the scope of our spelling lexicon containing around 200,000 entries. In order to get more specific numbers, we also manually labeled a query data set that contains 2,323 randomly sampled queries and 6,318 terms. In this data set, the ratio of out-of-vocabulary (OOV) terms is 17.4%, which is very similar to the overall distribution. However, only 25.3% of these OOV terms are identified to be misspelled, which occupy 85% of the overall spelling errors. All these statistics indicate that accurate OOV term classification is of crucial importance to good query spelling correction performance.

Cucerzan and Brill (2004) first investigated this issue and proposed to use query logs to infer correct spellings of misspelled terms. Their principle can be summarized as follows: given an input query string *q*, finding a more probable query *c* than *q* within a confusion set of *q*, in which the edit distance between each element and *q* is less than a given threshold. They reported good recall for misspelled terms, but without detailed discussions on accurate classification of valid out-of-vocabulary terms and misspellings. In Li's work, distributional similarity metrics estimated from query logs were proposed to be used to discriminate high-frequent spelling errors such as *massenger* from valid out-of-vocabulary terms such as *biocycle*. But this method suffers from the data sparseness problem: sufficient amounts of occurrences of every possible misspelling and valid terms are required to make good estimation of distributional similarity metrics; thus this method does not work well for rarely-used out-of-vocabulary search terms and uncommon misspellings.

In this paper we propose to use web search results to further improve the performance of query spelling correction models. The key contribution of our work is to identify that the dynamic online search results can serve as additional evidence to determine users' intended spelling of a given term. The information in web search results we used includes the number of pages matched for the query, the term distribution in the web page snippets and URLs. We studied two schemes to make use of the returning results of a web search engine. The first one only exploits indicators of the input query's returning results, while the other also looks at other potential correction candidate's search results. We performed extensive evaluations on a query set randomly sampled from search engines' daily query logs, and experimental results show that we can achieve 35.4% overall error rate reduction and 18.2% relative *F*-measure improvement on OOV misspelled terms.

The rest of the paper is structured as follows. Section 2 details other related work of spelling correction research. In section 3, we show the intuitive motivations to use web search results for the query spelling correction. After presenting the formal statement of the query spelling correction problem in Section 4, we describe our approaches that use machine learning methods to integrate statistical features from web search results in Section 5. We present our evaluation methods for the proposed methods and analyze their performance in Section 6. Section 7 concludes the paper.

2 Related Work

Spelling correction models in most previous work were constructed based on conventional task settings. Based on the focus of these task settings, two lines of research have been applied to deal with non-word errors and real-word errors respectively.

Non-word error spelling correction is focused on the task of generating and ranking a list of possible spelling corrections for each word not existing in a spelling lexicon. Traditionally candidate ranking is based on manually tuned scores such as assigning alternative weights to different edit operations or leveraging candidate frequencies (Damerau, 1964; Levenshtein, 1966). In recent years, statistical models have been widely used for the tasks of natural language processing, including spelling correction task. (Brill and Moore, 2000) presented an improved error model over the one proposed by (Kernighan et al., 1990) by allowing generic string-to-string edit operations, which helps with modeling major cognitive errors such as the confusion between *le* and *al*. Via explicit modeling of phonetic information of English words, (Toutanova and Moore, 2002) further investigated this issue. Both of them require misspelled/correct word pairs for training, and the latter also needs a pronunciation lexicon, but recently (Ahmad and Kondrak, 2005) demonstrated that it is also possible to learn such models automatically from query logs with the EM algorithm, which is similar to work of (Martin, 2004), learning from a very large corpus of raw text for removing non-word spelling errors in large corpus. All the work for non-word spelling correction focused on the current word itself without taking into account contextual information.

Real-word spelling correction is also referred to be context sensitive spelling correction (CSSC), which tries to detect incorrect usage of valid words in certain contexts. Using a pre-defined confusion set is a common strategy for this task, such as in the work of (Golding and Roth, 1996) and (Mangu and Brill, 1997). Opposite to non-word spelling correction, in this direction only contextual evidences were taken into account for modeling by assuming all spelling similarities are equal.

The complexity of query spelling correction task requires the combination of these types of evidence, as done in (Cucerzan and Brill, 2004; Li et al., 2006). One important contribution of our work is that we use web search results as extended contextual information beyond query strings by taking advantage of application specific knowledge. Although the information used in our methods can all be accessed in a search engine's web archive, such a strategy involves web-scale data processing which is a big engineering challenge, while our method is a light-weight solution to this issue.

3 Motivation

When a spelling correction model tries to make a decision whether to make a suggestion *c* to a query *q*, it generally needs to leverage two types of evidence: the similarity between *c* and *q*, and the validity plausibility of *c* and *q*. All the previous work estimated plausibility of a query based on the query string itself – typically it is represented as the string probability, which is further decomposed into production of consecutive n-gram probabilities. For example, both the work of (Cucerzan and Brill, 2004; Li et al., 2006) used n-gram statistical language models trained from search engine's query logs to estimate the query string probability.

In the following, we will show that the search results for a query can serve as a feedback mechanism to provide additional evidences to make better spelling correction decisions. The usefulness of web search results can be two-fold:

First, search results can be used to validate query terms, especially those not popular enough in query logs. One case is the validation for navigational queries (Broder, 2004). Navigational queries usually contain terms that are key parts of destination URLs, which may be out-of-vocabulary terms since there are millions of sites on the web. Because some of these navigational terms are very relatively rare in query logs, without knowledge of the special navigational property of a term, a query spelling correction model might confuse them with other low-frequency misspellings. But such information can be effectively obtained from the URLs of retrieved web pages. Inferring navigational queries through term-URL matching thus can help reduce the chance that the spelling correction model changes an uncommon web site name into popular search term, such as from *innovet* to *innovate*. Another example is that search results can be used in identifying acronyms or other abbreviations. We can observe some clear text patterns that relate abbreviations to their full spellings in the search results as shown in Figure 1. But such mappings cannot easily be obtained from query logs.

Figure 1. Sample search results for *SARS*

Second, search results can help verify correction candidates. The terms appearing in search results, both in the web page titles and snippets, provide additional evidences for users intention. For example, if a user searches for a misspelled query *vaccum cleaner* on a search engine, it is very likely that he will obtain some search results containing the correct term *vacuum* as shown in Figure 2. This can be attributed to the collective link text distribution on the web – many links with misspelled text point to sites with correct spellings. Such evidences can boost the confidence of a spelling correction model to suggest *vacuum* as a correction.

Figure 2. Sample search results for *vaccum cleaner*

The number of matched pages can be used to measure the popularity of a query on the web, which is similar to term frequencies occurring in query logs, but with broader coverage. Poor correction candidates can usually be verified by a smaller number of matched web pages.

Another observation is that the documents retrieved with correctly-spelled query and misspelled ones are similar to some extent in the view of term distribution. Both the web retrieval results of *vacuum* and *vaccum* contain terms such as *cleaner*, *pump*, *bag* or *systems*. We can take this similarity as an evidence to verify the spelling correction results.

4 Problem Statement

Given a query q, a spelling correction model is to find a query string c that maximizes the posterior probability of c given q within the confusion set of q. Formally we can write this as follows:

$$c^* = \underset{c \in C}{\textbf{argmax}}\; Pr(c|q) \tag{1}$$

where C is the confusion set of q. Each query string c in the confusion set is a correction candidate for q, which satisfies the constraint that the spelling similarity between c and q is within given threshold δ.

In this formulation, the error detection and correction are performed in a unified way. The query q itself always belongs to its confusion set C, and when the spelling correction model identifies a more probable query string c in C which is different from q, it claims a spelling error detected and makes a correction suggestion c.

There are two tasks in this framework. One is how to learn a statistical model to estimate the conditional probability $Pr(c|q)$, and the other is how to generate confusion set C of a given query q.

4.1 Maximum Entropy Model for Query Spelling Correction

We take a feature-based approach to model the posterior probability $Pr(c|q)$. Specifically we use the maximum entropy model (Berger et al., 1996) for this task:

$$Pr(c|q) = \frac{\exp(\sum_{i=1}^{N} \lambda_i f_i(c,q))}{\sum_c \exp(\sum_{i=1}^{N} \lambda_i f_i(c,q))} \tag{2}$$

where $\sum_c \exp(\sum_{i=1}^{N} \lambda_i f_i(c,q))$ is the normalization factor; $f_i(c,q)$ is a feature function defined over query q and correction candidate c , while λ_i is the corresponding feature weight. λs can be optimized using the numerical optimization algorithms such as the Generalized Iterative Scaling (GIS) algorithm (Darroch and Ratcliff, 1972) by maximizing the posterior probability of the training set which contains a manually labeled set of query-truth pairs:

$$\lambda^* = \operatorname{argmax} \sum_{c,q} \log Pr_\lambda(c|q) \tag{3}$$

The advantage of maximum entropy model is that it provides a natural way and unified framework to integrate all available information sources. This property is well fit for our task in which we are using a wide variety of evidences based on lexicon, query log and web search results.

4.2 Correction Candidate Generation

Correction candidate generation for a query q can be decomposed into two phases. In the first phase, correction candidates are generated for each term in the query from a term-base extracted from query logs. This task can leverage conventional spelling correction methods such as generating candidates based on edit distance (Cucerzan and Brill, 2004) or phonetic similarity (Philips, 1990). Then the correction candidates of the entire query are generated by composing the correction candidates of each individual term. Let $q = w_1 \cdots w_n$, and the confusion set of w_i is C_{w_i}, then the confusion set of q is $C_{w_1} \otimes C_{w_2} \otimes \cdots \otimes C_{w_n}$[1]. For example, for a query $q = w_1 w_2$, w_1 has candidates c_{11} and c_{12}, while w_2 has candidates c_{21} and c_{22}, then the confusion set C is $\{c_{11}c_{21}, c_{11}c_{22}, c_{12}c_{21}, c_{12}c_{22}\}$.

[1] For denotation simplicity, we do not cover compound and composition errors here.

The problem of this method is the size of confusion set C may be huge for multi-term queries. In practice, one term may have hundreds of possible candidates, then a query containing several terms may have millions. This might lead to impractical search and training using the maximum entropy modeling method. Our solution to this problem is to use *candidate pruning*. We first roughly rank the candidates based on the statistical n-gram language model estimated from query logs. Then we only choose a subset of C that contains a specified number of top-ranked (most probable) candidates to present to the maximum entropy model for offline training and online re-ranking, and the number of candidates is used as a parameter to balance top-line performance and run-time efficiency. This subset can be efficiently generated as shown in (Li et al., 2006).

5 Web Search Results based Query Spelling Correction

In this section we will describe in detail the methods for use of web search results in the query spelling correction task. In our work we studied two schemes. The first one only employs indicators of the input query's search results, while the other also looks at the most probable correction candidates' search results. For each scheme, we extract additional scheme-specific features from the available search results, combine them with baseline features and construct a new maximal model to perform candidate ranking.

5.1 Baseline model

We denote the maximum entropy model based on baseline model feature set as M0 and the feature set S0 derived from the latest state of the art works of (Li et al., 2006), where S0 includes the features mostly concerning the statistics of the query terms and the similarities between query terms and their correction candidates.

5.2 Scheme 1: Using search results for input query only

In this scheme we build more features for each correction candidate (including input query q itself) by distilling more evidence from the search results of the query. S1 denotes the augmented feature set, and M1 denotes the maximum entropy model based on S1. The features are listed as follows:

1. **Number of pages returned**: the number of web search pages retrieved by a web search engine, which is used to estimate the popularity of query. This feature is only for q.
2. **URL string**: Binary features indicating whether the combination of terms of each candidate is in the URLs of top retrieved documents. This feature is for all candidates.
3. **Frequency of correction candidate term**: the number of occurrences of modified terms in the correction candidate found in the title and snippet of top retrieved documents based on the observation that correction terms possibly co-occur with their misspelled ones. This feature is invalid for q.
4. **Frequency of query term**: the number of occurrences of each term of q found in the title or snippet of the top retrieved documents, based on the observation that the correct terms always appear frequently in their search results.
5. **Abbreviation pattern**: Binary features indicating whether inputted query terms might be abbreviations according to text patterns in search results.

5.3 Scheme 2: Using both search results of input query and top-ranked candidate

In this scheme we extend the use of search results both for query q and for top-ranked candidate c other than q determined by M1. First we submit a query to a search engine for the initial retrieval to obtain one set of search results R_q, then use M1 to find the best correction candidate c other than q. Next we perform a second retrieval with c to obtain another set of search results R_c. Finally additional features are generated for each candidate based on R_c, then a new maximum entropy model M2 is built to re-rank the candidates for a second time. The entire process can be schematically shown in Figure 3.

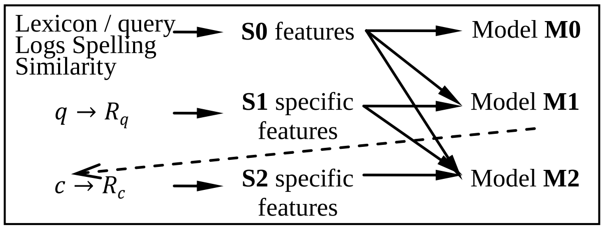

Figure 3. Relations of models and features

where R_q is the web search results of query q; R_c is the web search results of c which is the top-ranked correction of q suggested by model M1.

The new feature set denoted with S2 is a set of document similarities between R_q and R_c, which includes different similarity estimations between the query and its correction at the document level using merely cosine measure based on term frequency vectors of R_q and R_c.

6 Experiments

6.1 Evaluation Metrics

In our work, we consider the following four types of evaluation metrics:

- **Accuracy**: The number of correct outputs proposed by the spelling correction model divided by the total number of queries in the test set
- **Recall**: The number of correct suggestions for misspelled queries by the spelling correction model divided by the total number of misspelled queries in the test set
- **Precision**: The number of correct suggestions for misspelled queries proposed by the spelling correction model divided by the total number of suggestions made by the system
- **F-measure**: Formula $F = 2PR/(P + R)$ used for calculating the f-measure, which is essentially the harmonic mean of recall and precision

Any individual metric above might not be sufficient to indicate the overall performance of a query spelling correction model. For example, as in most retrieval tasks, we can trade recall for precision or vice versa. Although intuitively F might be in accordance with accuracy, there is no strict theoretical relation between these two numbers – there are conditions under which accuracy improves while F-measure may drop or be unchanged.

6.2 Experimental Setup

We used a manually constructed data set as gold standard for evaluation. First we randomly sampled 7,000 queries from search engine's daily query logs of different time periods, and had them manually labeled by two annotators independently. Each query is attached to a truth, which is either the query itself for valid queries, or a spelling correction for misspelled ones. From the annotation results that both annotators agreed with each other, we extracted 2,323 query-truth pairs as training set and 991 as test set. Table 1 shows the statistics of the data sets, in which E_q denotes the error rate of query and E_t denotes the error rate of term.

	# queries	# terms	E_q	E_t
Training set	2,323	6,318	15.0%	5.6%
Test set	991	2,589	12.8%	5.2%

Table 1. Statistics of training set and test set

In the following experiments, at most 50 correction candidates were used in the maximum entropy model for each query if there is no special explanation. The web search results were fetched from MSN's search engine. By default, top 100 retrieved items from the web retrieval results were used to perform feature extraction. A set of query log data spanning 9 months are used for collecting statistics required by the baseline.

6.3 Overall Results

Following the method as described in previous sections, we first ran a group of experiments to evaluate the performance of each model we discussed with default settings. The detailed results are shown in Table 2.

Model	Accuracy	Recall	Precision	F
M0	91.8%	60.6%	62.6%	0.616
M1	93.9%	64.6%	77.4%	0.704
M2	94.7%	66.9%	78.0%	0.720

Table 2. Overall Results

From the table we can observe significant performance boosts on all evaluation metrics of M1 and M2 over M0.

We can achieve 25.6% error rate reduction and 23.6% improvement in precision, as well as 6.6% relative improvement in recall, when adding S1 to M1. Paired t-test gives p-value of 0.002, which is significant to 0.01 level.

M2 can bring additional 13.1% error rate reduction and moderate improvement in precision, as well as 3.6% improvement in recall over M1, with paired t-test showing that the improvement is significant to 0.01 level.

6.4 Impact of Candidate number

Theoretically the number of correction candidates in the confusion set determines the accuracy and recall upper bounds for all models concerned in this paper. Performance might be hurt if we use a too small candidate number, which is because the corrections are separated from the confusion sets. These curves shown in Figure 4 and 5, include both theoretical bound (oracle) and actual performance of our described models. From the chart we can see that our models perform best when N_t is around 50, and when $N_t > 15$ the oracle recall and accuracy almost stay unchanged, thus the actual models' performance only benefits a little from larger N_t values. The missing part of recall is largely due to the fact that we are not able to generate truth candidates for some weird query terms rather than insufficient size of confusion set.

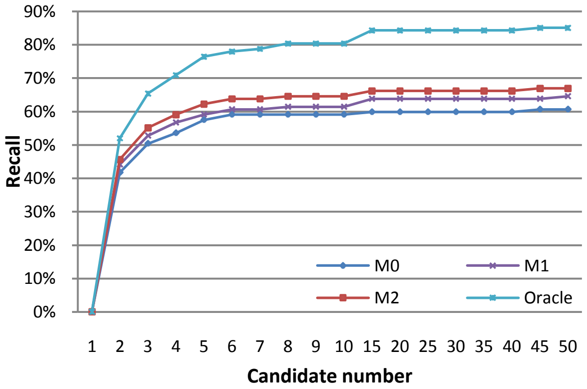

Figure 4. Recall versus candidate number

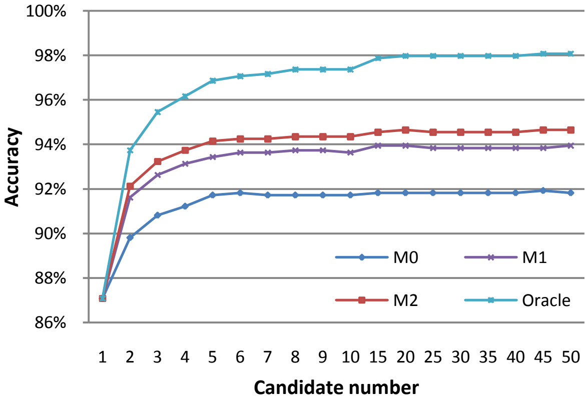

Figure 5. Accuracy versus candidate number

6.5 Discussions

We also studied the performance difference between in-vocabulary (IV) and out-of-vocabulary (OOV) terms when using different spelling correction models. The detailed results are shown in Table 3 and Table 4.

	Accuracy	Precision	Recall	F
M0	88.2%	77.1%	67.3%	0.718
M1	92.4%	88.5%	77.3%	0.825
M2	93.2%	91.6%	79.1%	0.849

Table 3. OOV Term Results

	Accuracy	Precision	Recall	F
M0	98.8%	44.0%	45.8%	0.449
M1	99.0%	62.5%	20.8%	0.313
M2	99.1%	75.0%	37.5%	0.500

Table 4. IV Term Results

The results show that M1 is very powerful to identify and correct OOV spelling errors compared with M0. Actually M1 is able to correct spelling errors such as *guiness*, whose frequency in query log is even higher than its truth spelling *guinness*. Since most spelling errors are OOV terms, this explains why the model M1 can significantly outperform the baseline. But for IV terms things are different. Although the overall accuracy is better, the F-measure of M1 is far lower than M0. M2 performs best for the IV task in terms of both accuracy and F-measure. However, IV spelling errors is so small a portion of the total misspelling (only 17.4% of total spelling errors in our test set) that the room for improvement is very small. This helps to explain why the performance gap between M1 and M0 is much larger than the one between M2 and M1, and shows the tendency that M1 prefer to identify and correct OOV misspellings in comparison to IV ones, which causes F-measure drop from M0 to M1; while by introducing more useful evidence, M2 outperforms better for both OOV and IV terms over M0 and M1.

Another set of statistics we collected from the experiments is the performance data of low-frequency terms when using the models proposed in this paper, since we believe that our approach would help make better classification of low-frequency search terms. As a case study, we identified in the test set all terms whose frequencies in our query logs are less than 800, and for these terms we calculated the error reduction rate of model M1 over the baseline model M0 at each interval of 50. The detailed results are shown in Figure 6. The clear trend can be observed that M1 can achieve larger error rate reduction over baseline for terms with lower frequencies. This is because the performance of baseline model drops for these terms when there are no reliable distributional similarity estimations available due to data sparseness in query logs, while M1 can use web data to alleviate this problem.

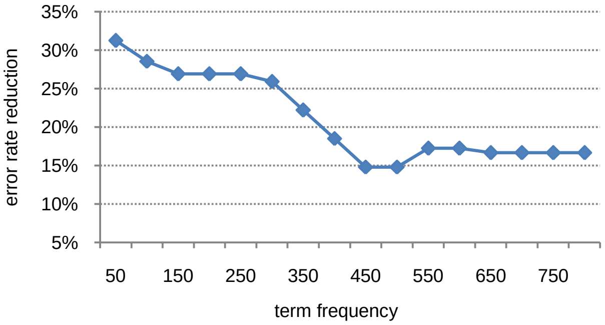

Figure 6. Error rate reduction of M1 over baseline for terms in different frequency ranges

7 Conclusions and Future Work

The task of query spelling correction is very different from conventional spelling checkers, and poses special research challenges. In this paper, we presented a novel method for use of web search results to improve existing query spelling correction models.

We explored two schemes for taking advantage of the information extracted from web search results. Experimental results show that our proposed methods can achieve statistically significant improvements over the baseline model which only relies on evidences of lexicon, spelling similarity and statistics estimated from query logs.

There is still further potential useful information that should be studied in this direction. For example, we can work on page ranking information of returning pages, because trusted or well-known sites with high page rank generally contain few wrong spellings. In addition, the term co-occurrence statistics on the returned snippet text are also worth deep investigation.

Abstract

The increasing use of large open-domain document sources is exacerbating the problem of ambiguity in named entities. This paper explores the use of a range of syntactic and semantic features in unsupervised clustering of documents that result from ad hoc queries containing names. From these experiments, we find that the use of robust syntactic and semantic features can significantly improve the state of the art for disambiguation performance for personal names for both Chinese and English.

1 Introduction

An ever-increasing number of question answering, summarization and information extraction systems are coming to rely on heterogeneous sets of documents returned by open-domain search engines from collections over which application developers have no control. A frequent special case of these applications involves queries containing named entities of various sorts and receives as a result a large set of possibly relevant documents upon which further deeper processing is focused. Not surprisingly, many, if not most, of the returned documents will be irrelevant to the goals of the application because of the massive ambiguity associated with the query names of people, places and organizations in large open collections. Without some means of separating documents that contain mentions of distinct entities, most of these applications will produce incorrect results. The work presented here, therefore, addresses the problem of automatically problem of automatically separating sets of news documents generated by queries containing personal names into coherent partitions.

The approach we present here combines unsupervised clustering methods with robust syntactic and semantic processing to automatically cluster returned news documents (and thereby entities) into homogeneous sets. This work follows on the work of Bagga & Baldwin (1998), Mann & Yarowsky (2003), Niu et al. (2004), Li et al. (2004), Pedersen et al. (2005), and Malin (2005). The results described here advance this work through the use of syntactic and semantic features that can be robustly extracted from the kind of arbitrary news texts typically returned from open-domain sources.

The specific contributions reported here fall into two general areas related to robustness. In the first, we explore the use of features extracted from syntactic and semantic processing at a level that is robust to changes in genre and language. In particular, we seek to go beyond the kind of bag of local words features employed in earlier systems (Bagga & Baldwin, 1998; Gooi & Allan, 2004; Pedersen et al., 2005) that did not attempt to exploit deep semantic features that are difficult to extract, and to go beyond the kind of biographical information (Mann & Yarowsky, 2003) that is unlikely to occur with great frequency (such as place of birth, or family relationships) in many of the documents returned by typical search engines. The second contribution involves the application of these techniques to both English and Chinese news collections. As we'll see, the methods are effective with both, but error analyses reveal interesting differences between the two languages.

Proceedings of the 2007 Joint Conference on Empirical Methods in Natural Language Processing and Computational Natural Language Learning, pp. 190–198, Prague, June 2007. ©2007 Association for Computational Linguistics

The paper is organized as follows. Section 2 addresses related work and compares our work with that of others. Section 3 introduces our new phrase-based features along two dimensions: from syntax to semantics; and from local sentential contexts to document-level contexts. Section 4 first describes our datasets and then analyzes the performances of our system for both English and Chinese. Finally, we draw some conclusions.

2 Previous work

Personal name disambiguation is a difficult problem that has received less attention than those topics that can be addressed via supervised learning systems. Most previous work (Bagga & Baldwin, 1998; Mann & Yarowsky, 2003; Li et al., 2004; Gooi & Allan, 2004; Malin, 2005; Pedersen et al., 2005; Byung-Won On and Dongwon Lee, 2007) employed unsupervised methods because no large annotated corpus is available and because of the variety of the data distributions for different ambiguous personal names.

Since it is common for a single document to contain one or more mentions of the ambiguous personal name of interest, there is a need to define the object to be disambiguated (the ambiguous object). In Bagga & Baldwin (1998), Mann & Yarowsky (2003) and Gooi & Allan (2004), an ambiguous object refers to a single entity with the ambiguous personal name in a given document. The underlying assumption for this definition is "one person per document" (all mentions of the ambiguous personal name in one document refer to the same personal entity in reality). In Niu et al. (2004) and Pedersen et al. (2005), an ambiguous object is defined as a mention of the ambiguous personal name in a corpus.

The first definition of the ambiguous object (document-level object) can include much information derived from that document, so that it can be represented by rich features. The later definition of the ambiguous object (mention-level object) can simplify the detection of the ambiguous object, but because of the limited coverage, it usually can use only local context (the text around the mention of the ambiguous personal name) and might miss some document-level information. The kind of name disambiguation based on mention-level objects really solves "within-document name ambiguity" and "cross-document name ambiguity" simultaneously, and often has a higher performance than the kind based on document-level objects because two mentions of the ambiguous personal name in a document are very likely to refer to the same personal entity. From our news corpus, we also found that mentions of the ambiguous personal name of interest in a news article rarely refer to multiple entities, so our system will focus on the name disambiguation for document-level objects.

In general, there are two types of information usually used in name disambiguation (Malin, 2005): personal information and relational information (explicit and implicit). Personal information gives biographical information about the ambiguous object, and relational information specifies explicit or implicit relations between the ambiguous object and other entities, such as a membership relation between "John Smith" and "Labor Party." Usually, explicit relational information can be extracted from local context, and implicit relational information is far away from the mentions of the ambiguous object. A hard case of name disambiguation often needs implicit relational information that provides a background for the ambiguous object. For example, if two news articles in consideration report an event happening in "Labor Party," this implicit relational information between "John Smith" and "Labor Party" can give a hint for name disambiguation if no personal or explicit relational information is available.

Bagga & Baldwin (1998), Mann & Yarowsky (2003), Gooi & Allan (2004), Niu et al. (2004), and Pedersen et al. (2005) explore features in local context. Bagga & Baldwin (1998), Gooi & Allan (2004), and Pedersen et al. (2005) use local token features; Mann & Yarowsky (2003) extract local biographical information; Niu et al. (2004) use co-occurring Named Entity (NE) phrases and NE relationships in local context. Most of these local contextual features are personal information or explicit relational information.

Li et al. (2004) and Malin (2005) consider named-entity disambiguation as a graph problem, and try to capture information related to the ambiguous object beyond local context, even implicit relational information. Li et al. (2004) use the EM algorithm to learn the global probability distribution among documents, entities, and representative mentions, and Malin (2005) constructs a social network graph to learn a similarity matrix.

In this paper, we also explore both personal and relational information beyond local context. But we achieve it with a different approach: extracting these types of information by means of syntactic and semantic processing. We not only extract local NE phrases as in Niu et al. (2004), but also use our entity co-reference system to extract accurate and representative NE phrases occurring in a document which may have a relation to the ambiguous object. At the same time, syntactic phrase information sometimes can overcome the imperfection of our NE system and therefore makes our disambiguation system more robust.

3 Overall Methodology

Our approach follows a common architecture for named-entity disambiguation: the detection of ambiguous objects, feature extraction and representation, similarity matrix learning, and finally clustering.

In our approach, all documents are preprocessed with a syntactic phrase chunker (Hacioglu, 2004) and the EXERT[1] system (Hacioglu et al. 2005; Chen & Hacioglu, 2006), a named-entity detection and co-reference resolution system that was developed for the ACE[2] project. A syntactic phrase chunker segments a sentence into a sequence of base phrases. A base phrase is a syntactic-level phrase that does not overlap another base phrase. Given a document, the EXERT system first detects all mentions of entities occurring in that document (named-entity detection) and then resolves the different mentions of an entity into one group that uniquely represents the entity (within-document co-reference resolution). The ACE 2005 task can detect seven types of named entities: person, organization, geo-political entity, location, facility, vehicle, and weapon; each type of named entity can occur in a document with any of three distinct formats: name, nominal construction, and pronoun. The F score of the syntactic phrase chunker, which is trained and tested on the Penn TreeBank, is 94.5, and the performances of the EXERT system are 82.9 (ACE value for named-entity detection) and 68.5 (ACE value for within-document co-reference resolution).

3.1 The detection of ambiguous objects

In our approach, we assume that the ambiguous personal name has already been determined by the application. Moreover, we adopt the policy of "one person per document" as in Bagga & Baldwin (1998), and define an ambiguous object as a set of target entities given by the EXERT system. A target entity is an entity that has a mention of the ambiguous personal name. Given the definition of an ambiguous object, we define a local sentence (or local context) as a sentence that contains a mention of any target entity.

3.2 Feature extraction and representation

Since considerable personal and relational information related to the ambiguous object resides in the noun phrases in the document, such as the person's job and the person's location, we attempt to capture this noun phrase information along two dimensions: from syntax to semantics, and from local contexts to document-level contexts.

Base noun phrase feature: To keep this feature focused, we extract only noun phrases occurring in the local sentences and the summarized sentences (the headline + the first sentence of the document) of the document. The local sentences usually include personal or explicit relational information about the ambiguous object, and the summarized sentences of a news document usually give a short summary of the whole news story. With the syntactic phrase chunker, we develop two base noun phrase models: (i) ***Contextual base noun phrases (Contextual bnp)***, the base noun phrases in the local sentences; (ii) ***Summarized base noun phrases (Summarized bnp)***, the base noun phrases in the local sentences and the summarized sentences. A base noun phrase of interest serves as an element in the feature vector.

Named-Entity feature: Given the EXERT system, a direct and simple way to extract some semantic information is to use the named entities detected in the document. Based on their relationship to the ambiguous personal name, the named entities identified in a text can be divided into three categories:

(i) Target entity: an entity that has a mention of the ambiguous personal name. Target entities often include some personal information about the ambiguous object, such as the title, position, and so on.

Figure 1: A Sample of Feature Extraction

(ii) Local entity: an entity other than a target entity that has a mention occurring in any local sentence. Local entities often include entities that are closely related to the ambiguous object, such as employer, location and co-workers.

(iii) Non-local entity: an entity that is not either the local entity or the target entity. Non-local entities are often implicitly related to the ambiguous object and provide background information for the ambiguous object.

To assess how important these entities are to named-entity disambiguation, we create two kinds of entity models: (i) ***Contextual entities:*** the entities in the feature vector are target entities and local entities; (ii) ***Document entities:*** the entities in the feature vector include all entities in the document including target entities, local entities and non-local entities.

Since a given entity can be represented by many mentions in a document, we choose a single representative mention to represent each entity. The representative mention is selected according to the following ordered preference list: longest NAME mention, longest NOMINAL mention. A representative mention phrase serves as an element in a feature vector.

Although the mentions of contextual entities often overlap with contextual base noun phrases, the representative mention of a contextual entity often goes beyond local sentences, and is usually the first or longest mention of that contextual entity. Compared to contextual base noun phrases, the representative mention of a contextual entity often includes more detail and accurate information about the entity. On the other hand, the contextual base noun phrase feature detects all noun phrases occurring in local sentences that are not limited to the seven types of named entities discovered by the EXERT system. Compared to the contextual entity feature, the contextual base noun phrase feature is more general and can sometimes overcome errors propagated from the named-entity system.

To make this more concrete, the feature vectors for a document containing “John Smith” are highlighted in Figure 1. The superscript number for each phrase refers to the sentence where the phrase is located, and we assume that the syntactic phrase chunker and the EXERT system work perfectly.

3.3 Similarity matrix learning

Given a pair of feature vectors consisting of phrase-based features, we need to choose a similarity scheme to calculate the similarity. Because of the word-space delimiter in English, the feature vector for an English document comprises phrases, whereas that for a Chinese document comprises tokens. There are a number of similarity schemes for learning a similarity matrix from token-based feature vectors, but there are few schemes for phrase-based feature vectors.

Cohen et al. (2003) compared various similarity schemes for the task of matching English entity names and concluded that the hybrid scheme they call SoftTFIDF performs best. SoftTFIDF is a token-based similarity scheme that combines a standard TF-IDF weighting scheme with the Jaro-Winkler distance function. Since Chinese feature vectors are token-based, we can directly use SoftTFIDF to learn the similarity matrix. However, English feature vectors are phrase-based, so we need to run SoftTFIDF iteratively and call it “two-level SoftTFIDF.” First, the standard SoftTFIDF is used to calculate the similarity between phrases in the pair of feature vectors; in the second phase, we reformulate the standard SoftTFIDF to calculate the similarity for the pair of feature vectors.

First, we introduce the standard SoftTFIDF. In a pair of feature vectors *S* and *T*, *S* = ($s_1, \dots, s_n$) and *T* = ($t_1, \dots, t_m$). Here, s_i (i = 1…n) and t_j (j = 1…m) are substrings (tokens). Let *CLOSE*(*θ; S;T*) be the set of substrings $w \in S$ such that there is some $v \in T$ satisfying *dist*(*w; v*) > θ. The Jaro-Winkler distance function (Winkler, 1999) is *dist*(;). For $w \in CLOSE(\theta;\ S;T)$, let *D*(*w; T*) = $\max_{v \in T} dist(w;v)$. Then the standard SoftTFIDF is computed as

$$\mathrm{SoftTFIDF}\,(S,T) =$$

$$\sum\nolimits_{w \in CLOSE(\theta;S;T)} \mathrm{V}(w,\ S) \times \mathrm{V}(w,\ T) \times \mathrm{D}(w,\ T)$$

$$\mathrm{V'}(w,\ S) = \log\,(\mathrm{TF}_{w,S} + 1) \times \log\,(\mathrm{IDF}_{w})$$

$$\mathrm{V}\,(w,\ S) = \frac{\mathrm{V}\ \ (w,\ S)}{\sqrt{\sum\nolimits_{\mathrm{w} \in S} \mathrm{V}\,(w,\ S)^2}}$$

where $\mathrm{TF}_{w,S}$ is the frequency of substrings *w* in *S*, and IDF_w is the inverse of the fraction of documents in the corpus that contain *w*. In computing the similarity for the English phrase-based feature vectors, in the second step of “two-level SoftTFIDF,” the substring *w* is a phrase and *dist* is the standard SoftTFIDF.

So far, we have developed several feature models and learned the corresponding similarity matrices, but clustering usually needs only one unique similarity matrix. Since a feature may have different effects for the disambiguation depending on the ambiguous personal name in consideration, to achieve the best disambiguation ability, each personal name may need its own weighting scheme to combine the given similarity matrices. However, learning that kind of weighting scheme is very difficult, so in this paper, we simply combine the similarity matrices, assigning equal weight to each one.

3.4 Clustering

Although clustering is a well-studied area, a remaining research problem is to determine the optimal parameter setting during clustering, such as the number of clusters or the stop-threshold, a problem that is important for real tasks and that is not at all trivial.

Since the focus of this paper is only on feature development, we simply employ a clustering method that can reflect the quality of the similarity matrix for clustering. Here, we choose agglomerative clustering with a single linkage. Since each personal name may need a different parameter setting, to test the importance of the parameter setting for clustering, we use two kinds of stop-thresholds for agglomerative clustering in our experiments: first, to find the optimal stop-threshold for any ambiguous personal name and for each feature model, we run agglomerative clustering with all possible stop-thresholds, and choose the one that has the best performance as the optimal stop-threshold; second, we use a fixed stop-threshold acquired from development data.

4 Performance

4.1 Data

To capture the real data distribution, we use two sets of naturally occurring data: Bagga's corpus and the Boulder Name corpus, which is a news corpus locally acquired from a web search. Bagga's corpus is a document collection for the English personal name "John Smith" that was used by Bagga & Baldwin (1998). There are 256 articles that match the "/John.*?Smith/" regular expression in 1996 and 1997 editions of the *New York Times*, and 94 distinct "John Smith" personal entities are mentioned. Of these, 83 "John Smiths" are mentioned in only one article (singleton clusters containing only one object), and 11 other "John Smiths" are mentioned several times in the remaining 173 articles (non-singleton clusters containing more than one object). For the task of cross-document co-reference, Bagga & Baldwin (1998) chose 24 articles from 83 singleton clusters, and 173 other articles in 11 non-singleton clusters to create the final test data set – Bagga's corpus.

We collected the Boulder Name corpus by first selecting four highly ambiguous personal names each in English and Chinese. For each personal name, we retrieved the first non-duplicated 100 news articles from Google (Chinese) or Google news (English). There are four data sets for English personal names and four data sets for Chinese personal names: James Jones, John Smith, Michael Johnson, Robert Smith, and Li Gang, Li Hai, Liu Bo, Zhang Yong.

Compared to Bagga's corpus, which is limited to the *New York Times*, the documents in the Boulder Name corpus were collected from different sources, and hence are more heterogeneous and noisy. This variety in the Boulder Name corpus reflects the distribution of the real data and makes named-entity disambiguation harder.

For each ambiguous personal name in both corpora, the gold standard clusters have a long-tailed distribution - a high percentage of singleton clusters plus a few non-singleton clusters. For example, in the 111 documents containing "John Smith" in the Boulder Name corpus, 53 "John Smith" personal entities are mentioned. Of them, 37 "John Smiths" are mentioned only once. The long-tailed distribution brings some trouble to clustering, since in many clustering algorithms a singleton cluster is considered as a noisy point and therefore is ignored.

4.2 Corpus performance

Because of the long tail of the data set, we design a baseline using one cluster per document. To evaluate our disambiguation system, we choose the B-cubed scoring method that was used by Bagga & Baldwin (1998).

In order to compare our work to that of others, we re-implement the model used by Bagga & Baldwin (1998). First, extracting all local sentences produces a summary about the given ambiguous object. Then, the object is represented by the tokens in its summary in the format of a vector, and the tokens in the feature vector are in their morphological root form and are filtered by a stop-word dictionary. Finally, the similarity matrix is learned by the TF-IDF method.

Because both "two-level SoftTFIDF" and agglomerative clustering require a parameter setting, for each language, we reserve two ambiguous personal names from the Boulder Name corpus as development data (John Smith, Michael Johnson, Li Gang, Zhang Yong), and the other data are reserved as test data: Bagga's corpus and the other personal names in the Boulder Name corpus (Robert Smith, James Jones, Li Hai, Liu Bo).

For any ambiguous personal name and for each feature model, we find the optimal stop-threshold for agglomerative clustering, and show the corresponding performances in Table 1, Table 2 and Table 3. However, for the most robust feature model, Bagga + summarized bnp + document entities, we learn the fixed stop-threshold for agglomerative clustering from the development data (0.089 for English data and 0.078 for Chinese data), and show the corresponding performances in Table 4.

4.2.1 Performance on Bagga's corpus

Table 1 shows the performance of each feature model for Bagga's corpus with the optimal stop-threshold. The metric here is the B-cubed F score (precision/recall).

Because of the difference between Bagga's resources and ours (different versions of the named-entity system and different dictionaries of the morphological root and the stop-words), our best

B-cubed F score for Bagga's model is 80.3— 4.3 percent lower than the best performance reported by Bagga & Baldwin (1998): 84.6.

From Table 1, we found that the syntactic features (contextual bnp and summarized bnp) and semantic features (contextual entities and document entities) consistently improve the performances, and all performances outperform the best result reported by Bagga & Baldwin (1998): 84.6

Model	B-cubed performance
Gold standard cluster #	35
Baseline	30.17 (100.00/17.78)
Bagga	80.32 (94.77/69.70)
Bagga + contextual bnp	89.16 (89.18/89.13)
Bagga + summarized bnp	89.59 (92.60/86.78)
Bagga + summarized bnp + contextual entities	89.60 (87.16/92.18)
Bagga + summarized bnp + document entities	92.02 (93.10/90.97)

Table 1: Performances for Bagga's corpus with the optimal stop-threshold

Chinese Name	Li Gang (dev)	Zhang Yong (dev)	Li Hai (test)	Liu Bo (test)	Average performance
Bagga + summarized bnp + document entities	99.06 *(99.50)*	94.56 (*94.56*)	98.25 (*98.57*)	89.18 (*97.02*)	95.26 (*97.41*)

Table 4: Performances for the Boulder Name corpus with the fixed stop-threshold

4.2.2 Performance on the Boulder Name corpus

Table 2 and Table 3 show the performance of each feature model with the optimal stop-threshold for the English and Chinese Boulder Name corpora, respectively. The metric is the B-cubed F score and the number in brackets is the corresponding cluster number. Since the same feature model has different contributions for different ambiguous personal names, we list the average performances for all ambiguous names in the last column in both tables.

Comparing Table 2 and Table 3, we find that Bagga's model has different performances for the English and Chinese corpora. That means that contextual tokens have different contributions in the two languages. There are three apparent causes for this phenomenon. The first concerns the frequency of pronouns in English vs. pro-drop in Chinese. The typical usage of pronouns in English requires an accurate pronoun co-reference resolution that is very important for the local sentence extraction in Bagga's model. In the Boulder Name corpus, we found that ambiguous personal names occur in Chinese much more frequently than in English. For example, the string "Liu Bo" occurs 876 times in the "Liu Bo" data, but the string "John Smith" occurs only 161 times in the "John Smith" data. The repetition of ambiguous personal names in Chinese reduces the burden on pronoun co-reference resolution and hence captures local information more accurately.

The second factor is the fact that tokens in Bagga's model for Chinese are words, but a Chinese word is a unit bigger than an English word, and may contain more knowledge. For example, "the White House" has three words in English, and a word in Chinese. Since Chinese named-entity detection can be considered a sub-problem of Chinese word segmentation, a word in Chinese can catch partial information about named entities.

Finally, compared to Chinese news stories, English news stories are more likely to mention persons marginal to the story, and less likely to give the complete identifying information about them in local context. Those phenomena require more background information or implicit relational information to improve English named-entity disambiguation.

From Table 2 and Table 3, we see that the average performance of all ambiguous personal names is increased (from 87.42 to 93.77 for English and from 94.70 to 97.41 for Chinese) by incorporating more information: contextual bnp (contextual base noun phrases), summarized bnp (summarized base noun phrases), contextual entities, and document entities. This indicates that the phrase-based features, the syntactic and semantic noun phrases, are very useful for disambiguation.

From Table 2 and Table 3, we also see that the phrase-based features can improve the average performance, but not always for all ambiguous personal names. For example, the feature model "Bagga + summarized bnp + contextual entities" hurts the performance for "Robert Smith." As we mentioned above, the Boulder Name corpus is heterogeneous, so each feature does not make the same contribution to the disambiguation for any ambiguous personal name. What we need to do is to find a feature model that is robust for all ambiguous personal names.

In Table 4, we choose the last feature model—Bagga + summarized bnp + document entities—as the final feature model, learn the fixed stop-threshold for clustering from the development data, and show the corresponding performances as B-cubed F scores. The performances in italics are the performances with the optimal stop-threshold. From Table 4, we find that, with the exception of "Robert Smith" and "Liu Bo," the performances for other ambiguous personal names with the fixed threshold are close to the corresponding best performances.

5 Conclusion

This work has explored the problem of personal named-entity disambiguation for news corpora. Our experiments extend token-based information to include noun phrase-based information along two dimensions: from syntax to semantics, and from local sentential contexts to document-level contexts. From these experiments, we find that rich and broad information improves the disambiguation performance considerably for both English and Chinese. In the future, we will continue to explore additional semantic features that can be robustly extracted, including features derived from semantic relations and semantic role labels, and try to extend our work from news articles to web pages that include more noisy information. Finally, we have focused here primarily on feature development and not on clustering. We believe that the skewed long-tailed distribution that characterizes this data requires the use of clustering algorithms tailored to this distribution. In particular, the large number of singleton clusters is an issue that confounds the standard clustering methods we have been employing.

Abstract

Trigram language models are compressed using a Golomb coding method inspired by the original Unix spell program. Compression methods trade off space, time and accuracy (loss). The proposed HashTBO method optimizes space at the expense of time and accuracy. Trigram language models are normally considered memory hogs, but with HashTBO, it is possible to squeeze a trigram language model into a few megabytes or less. HashTBO made it possible to ship a trigram contextual speller in Microsoft Office 2007.

1 Introduction

This paper will describe two methods of compressing trigram language models: HashTBO and ZipTBO. ZipTBO is a baseline compression method that is commonly used in many applications such as the Microsoft IME (Input Method Editor) systems that convert Pinyin to Chinese and Kana to Japanese.

Trigram language models have been so successful that they are beginning to be rolled out to applications with millions and millions of users: speech recognition, handwriting recognition, spelling correction, IME, machine translation and more. The EMNLP community should be excited to see their technology having so much influence and visibility with so many people. Walter Mossberg of the Wall Street Journal called out the contextual speller (the blue squiggles) as one of the most notable features in Office 2007:

There are other nice additions. In Word, Outlook and PowerPoint, there is now contextual spell checking, which points to a wrong word, even if the spelling is in the dictionary. For example, if you type "their" instead of "they're," Office catches the mistake. It really works.[1]

The use of contextual language models in spelling correction has been discussed elsewhere: (Church and Gale, 1991), (Mays *et al*, 1991), (Kukich, 1992) and (Golding and Schabes, 1996). This paper will focus on how to deploy such methods to millions and millions of users. Depending on the particular application and requirements, we need to make different tradeoffs among:

1. Space (for compressed language model),
2. Runtime (for *n*-gram lookup), and
3. Accuracy (losses for *n*-gram estimates).

HashTBO optimizes space at the expense of the other two. We recommend HashTBO when space concerns dominate the other concerns; otherwise, use ZipTBO.

There are many applications where space is extremely tight, especially on cell phones. HashTBO was developed for contextual spelling in Microsoft Office 2007, where space was the key challenge. The contextual speller probably would not have shipped without HashTBO compression.

We normally think of trigram language models as memory hogs, but with HashTBO, a few megabytes are more than enough to do interesting things with trigrams. Of course, more memory is always better, but it is surprising how much can be done with so little.

For English, the Office contextual speller started with a predefined vocabulary of 311k word types and a corpus of 6 billion word tokens. (About a

Proceedings of the 2007 Joint Conference on Empirical Methods in Natural Language Processing and Computational Natural Language Learning, pp. 199–207, Prague, June 2007.

third of the words in the vocabulary do not appear in the corpus.) The vocabularies for other languages tend to be larger, and the corpora tend to be smaller. Initially, the trigram language model is very large. We prune out small counts (8 or less) to produce a starting point of 51 million trigrams, 14 million bigrams and 311k unigrams (for English). With extreme Stolcke, we cut the 51+14+0.3 million *n*-grams down to a couple million. Using a Golomb code, each *n*-gram consumes about 3 bytes on average.

With so much Stolcke pruning and lossy compression, there will be losses in precision and recall. Our evaluation finds, not surprisingly, that compression matters most when space is tight. Although HashTBO outperforms ZipTBO on the spelling task over a wide range of memory sizes, the difference in recall (at 80% precision) is most noticeable at the low end (under 10MBs), and least noticeable at the high end (over 100 MBs). When there is plenty of memory (100+ MBs), the difference vanishes, as both methods asymptote to the upper bound (the performance of an uncompressed trigram language model with unlimited memory).

2 Preliminaries

Both methods start with a TBO (trigrams with backoff) LM (language model) in the standard ARPA format. The ARPA format is used by many toolkits such as the CMU-Cambridge Statistical Language Modeling Toolkit.[2]

2.1 Katz Backoff

No matter how much data we have, we never have enough. Nothing has zero probability. We will see *n*-grams in the test set that did not appear in the training set. To deal with this reality, Katz (1987) proposed backing off from trigrams to bigrams (and from bigrams to unigrams) when we don't have enough training data.

Backoff doesn't have to do much for trigrams that were observed during training. In that case, the backoff estimate of $P(w_i|w_{i-2}w_{i-1})$ is simply a discounted probability $P_d(w_i|w_{i-2}w_{i-1})$.

The discounted probabilities steal from the rich and give to the poor. They take some probability mass from the rich *n*-grams that have been seen in training and give it to poor unseen *n*-grams that might appear in test. There are many ways to discount probabilities. Katz used Good-Turing smoothing, but other smoothing methods such as Kneser-Ney are more popular today.

Backoff is more interesting for unseen trigrams. In that case, the backoff estimate is:

$$\alpha(w_{i-2}w_{i-1})P_d(w_i|w_{i-1})$$

The backoff alphas (α) are a normalization factor that accounts for the discounted mass. That is,

$$\alpha(w_{i-2}w_{i-1}) = \frac{1-\sum_{w_i:C(w_{i-2}w_{i-1}w_i)} P(w_i|w_{i-2}w_{i-1})}{1-\sum_{w_i:C(w_{i-2}w_{i-1}w_i)} P(w_i|w_{i-1})}$$

where $C(w_{i-2}w_{i-1}w_i) > 0$ simply says that the trigram was seen in training data.

3 Stolcke Pruning

Both ZipTBO and HashTBO start with Stolcke pruning (1998).[3] We will refer to the trigram language model after backoff and pruning as a *pruned TBO LM*.

Stolcke pruning looks for *n*-grams that would receive nearly the same estimates via Katz backoff if they were removed. In a practical system, there will never be enough memory to explicitly materialize all *n*-grams that we encounter during training. In this work, we need to compress a large set of *n*-grams (that appear in a large corpus of 6 billion words) down to a relatively small language model of just a couple of megabytes. We prune as much as necessary to make the model fit into the memory allocation (after subsequent Hash-TBO/ZipTBO compression).

Pruning saves space by removing *n*-grams subject to a loss consideration:

1. Select a threshold θ.
2. Compute the performance loss due to pruning each trigram and bigram individually using the pruning criterion.
3. Remove all trigrams with performance loss less than θ
4. Remove all bigrams with no child nodes (trigram nodes) and with performance loss less than θ
5. Re-compute backoff weights.

[2] http://www.speech.cs.cmu.edu/SLM

[3] http://www.nist.gov/speech/publications/darpa98/html/lm20/lm20.htm

Stolcke pruning uses a loss function based on relative entropy. Formally, let P denote the trigram probabilities assigned by the original unpruned model, and let P' denote the probabilities in the pruned model. Then the relative entropy $D(P||P')$ between the two models is

$$-\sum_{w,h} P(w,h)[\log P'(w|h) - \log P(w,h)]$$

where h is the history. For trigrams, the history is the previous two words. Stolcke showed that this reduces to

$$-P(h)\{P(w|h) \\ [\log P(w|h') + \log \alpha'(h) - \log P(w|h)] \\ +[\log \alpha'(h) - \log \alpha(h)] \sum_{w:C(h,w)>0} P(w|h)\}$$

where $\alpha'(h)$ is the revised backoff weight after pruning and h' is the revised history after dropping the first word. The summation is over all the trigrams that were seen in training: $C(h,w) > 0$.

Stolcke pruning will remove *n*-grams as necessary, minimizing this loss.

3.1 Compression on Top of Pruning

After Stolcke pruning, we apply additional compression (either ZipTBO or HashTBO). ZipTBO uses a fairly straightforward data structure, which introduces relatively few additional losses on top of the pruned TBO model. A few small losses are introduced by quantizing the log likelihoods and the backoff alphas, but those losses probably don't matter much. More serious losses are introduced by restricting the vocabulary size, *V*, to the 64k most-frequent words. It is convenient to use byte aligned pointers. The actual vocabulary of more than 300,000 words for English (and more for other languages) would require 19-bit pointers (or more) without pruning. Byte operations are faster than bit operations. There are other implementations of ZipTBO that make different tradeoffs, and allow for larger *V* without pruning losses.

HashTBO is more heroic. It uses a method inspired by McIlroy (1982) in the original Unix Spell Program, which squeezed a word list of *N*=32,000 words into a PDP-11 address space (64k bytes). That was just 2 bytes per word!

HashTBO uses similar methods to compress a couple million *n*-grams into half a dozen megabytes, or about 3 bytes per *n*-gram on average (including log likelihoods and alphas for backing off). ZipTBO is faster, but takes more space (about 4 bytes per *n*-gram on average, as opposed to 3 bytes per *n*-gram). Given a fixed memory budget, ZipTBO has to make up the difference with more aggressive Stolcke pruning. More pruning leads to larger losses, as we will see, for the spelling application.

Losses will be reported in terms of performance on the spelling task. It would be nice if losses could be reported in terms of cross entropy, but the values output by the compressed language models cannot be interpreted as probabilities due to quantization losses and other compression losses.

4 McIlroy's Spell Program

McIlroy's spell program started with a hash table. Normally, we store the clear text in the hash table, but he didn't have space for that, so he didn't. Hash collisions introduce losses.

McIlroy then sorted the hash codes and stored just the interarrivals of the hash codes instead of the hash codes themselves. If the hash codes, *h*, are distributed by a Poisson process, then the interarrivals, *t*, are exponentially distributed:

$$\Pr(t) = \lambda e^{-\lambda t},$$

where $\lambda = \frac{N}{P}$. Recall that the dictionary contains *N*=32,000 words. *P* is the one free parameter, the range of the hash function. McIlroy hashed words into a large integer mod *P*, where *P* is a large prime that trades off space and accuracy. Increasing *P* consumes more space, but also reduces losses (hash collisions).

McIlroy used a Golomb (1966) code to store the interarrivals. A Golomb code is an optimal Huffman code for an infinite alphabet of symbols with exponential probabilities.

The space requirement (in bits per lexical entry) is close to the entropy of the exponential.

$$H = -\int_{t=0}^{\infty} \Pr(t) \log_2 \Pr(t)\, dt$$

$$\hat{H} = \left\lceil \frac{1}{\log_e 2} + \log_2 \frac{1}{\lambda} \right\rceil$$

The ceiling operator $\lceil\;\rceil$ is introduced because Huffman codes use an integer number of bits to encode each symbol.

We could get rid of the ceiling operation if we replaced the Huffman code with an Arithmetic code, but it is probably not worth the effort.

Lookup time is relatively slow. Technically, lookup time is $O(N)$, because one has to start at the beginning and add up the interarrivals to reconstruct the hash codes. McIlroy actually introduced a small table on the side with hash codes and offsets so one could seek to these offsets and avoid starting at the beginning every time. Even so, our experiments will show that HashTBO is an order of magnitude slower than ZipTBO.

Accuracy is also an issue. Fortunately, we don't have a problem with dropouts. If a word is in the dictionary, we aren't going to misplace it. But two words in the dictionary could hash to the same value. In addition, a word that is not in the dictionary could hash to the same value as a word that is in the dictionary. For McIlroy's application (detecting spelling errors), the only concern is the last possibility. McIlroy did what he could do to mitigate false positive errors by increasing P as much as he could, subject to the memory constraint (the PDP-11 address space of 64k bytes).

We recommend these heroics when space dominates other concerns (time and accuracy).

5 Golomb Coding

Golomb coding takes advantage of the sparseness in the interarrivals between hash codes. Let's start with a simple recipe. Let t be an interarrival. We will decompose t into a pair of a quotient (t_q) and a remainder (t_r). That is, let $t = t_q m + t_r$ where $t_q = \lfloor t/m \rfloor$ and $t_r = t \bmod m$. We choose m to be a power of two near $m \approx \left\lceil \frac{E[t]}{2} \right\rceil = \left\lceil \frac{P}{2N} \right\rceil$, where $E[t]$ is the expected value of the interarrivals, defined below. Store t_q in unary and t_r in binary.

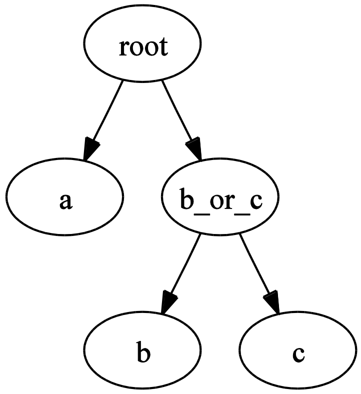
Binary codes are standard, but unary is not. To encode a number z in unary, simply write out a sequence of z-1 zeros followed by a 1. Thus, it takes z bits to encode the number z in unary, as opposed to $\log_2 z$ bits in binary.

This recipe consumes $t_q + \log_2 m$ bits. The first term is for the unary piece and the second term is for the binary piece.

Why does this recipe make sense? As mentioned above, a Golomb code is a Huffman code for an infinite alphabet with exponential probabilities. We illustrate Huffman codes for infinite alphabets by starting with a simple example of a small (very finite) alphabet with just three symbols: $\{a, b, c\}$. Assume that half of the time, we see a, and the rest of the time we see b or c, with equal probabilities:

Symbol	Code	Length	Pr
A	0	1	50%
B	10	2	25%
C	11	2	25%

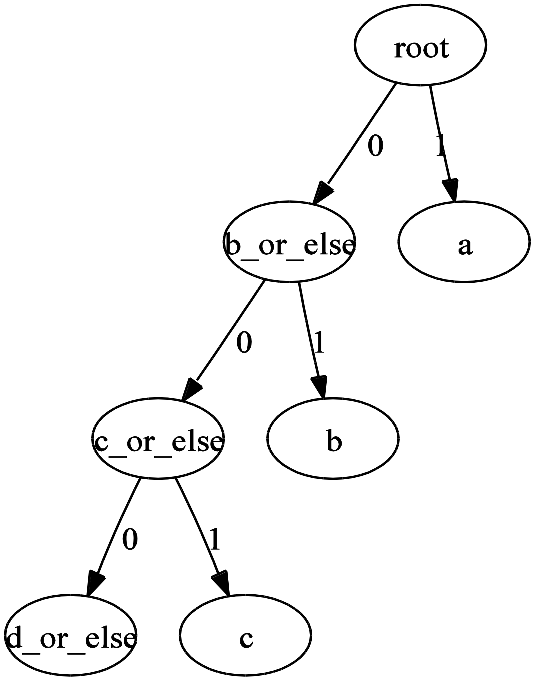
The Huffman code in the table above can be read off the binary tree below. We write out a 0 whenever we take a left branch and a 1 whenever we take a right branch. The Huffman tree is constructed so that the two branches are equally likely (or at least as close as possible to equally likely).



Now, let's consider an infinite alphabet where $\Pr(a) = \frac{1}{2}$, $\Pr(b) = \frac{1}{4}$ and the probability of the *t+1st* symbol is $\Pr(t) = (1-\beta)\beta^t$ where $\beta = \frac{1}{2}$. In this case, we have the following code, which is simply t in unary. That is, we write out $t-1$ zeros followed by a 1.

Symbol	Code	Length	Pr
A	1	1	2^{-1}
B	01	2	2^{-2}
C	001	3	2^{-3}

The Huffman code reduces to unary when the Huffman tree is left branching:



In general, β need not be ½. Without loss of generality, assume $\Pr(t) = (1-\beta)\beta^t$ where $\frac{1}{2} \leq \beta < 1$ and $t \geq 0$. β depends on $E[t]$, the expected value of the interarrivals:

$$E[t] = \frac{P}{N} = \frac{\beta}{1-\beta} \Rightarrow \beta = \frac{E[t]}{1+E[t]}$$

Recall that the recipe above calls for expressing t as $m \cdot t_q + t_r$ where $t_q = \lfloor \frac{t}{m} \rfloor$ and $t_r = t \bmod m$. We encode t_q in unary and t_r in binary. (The binary piece consumes $\log_2 m$ bits, since t_r ranges from 0 to m.)

How do we pick m? For convenience, let m be a power of 2. The unary encoding makes sense as a Huffman code if $\beta^m \approx \frac{1}{2}$.

Thus, a reasonable choice[4] is $m \approx \left\lceil \frac{E[t]}{2} \right\rceil$. If $\beta = \frac{E[t]}{1+E[t]}$, then $\beta^m = \frac{E[t]^m}{(1+E[t])^m} \approx 1 - \frac{m}{E[t]}$. Setting $\beta^m \approx \frac{1}{2}$, means $m \approx \frac{E[t]}{2}$.

6 HashTBO Format

The HashTBO format is basically the same as McIlroy's format, except that McIlroy was storing words and we are storing *n*-grams. One could store all of the n-grams in a single table, though we actually store unigrams in a separate table. An *n*-gram is represented as a key of *n* integers (offsets into the vocabulary) and two values, a log likelihood and, if appropriate, an alpha for backing off. We'll address the keys first.

6.1 HashTBO Keys

Trigrams consist of three integers (offsets into the Vocabulary): $w_1 w_2 w_3$. These three integers are mapped into a single hash between 0 and $P-1$ in the obvious way:

$$hash = (w_3 V^0 + w_2 V^1 + w_1 V^2) \bmod P$$

where V is vocabulary size. Bigrams are hashed the same way, except that the vocabulary is padded with an extra symbol for NA (not applicable). In the bigram case, w_3 is NA.

We then follow a simple recipe for bigrams and trigrams:

1. Stolcke prune appropriately
2. Let *N* be the number of n-grams
3. Choose an appropriate *P* (hash range)
4. Hash the *N* n-grams
5. Sort the hash codes
6. Take the first differences (which are modeled as interarrivals of a Poisson process)
7. Golomb code the first differences

We did not use this method for unigrams, since we assumed (perhaps incorrectly) that we will have explicit likelihoods for most of them and therefore there is little opportunity to take advantage of sparseness.

Most of the recipe can be fully automated with a turnkey process, but two steps require appropriate hand intervention to meet the memory allocation for a particular application:

1. Stolcke prune appropriately, and
2. Choose an appropriate *P*

[4] This discussion follows slide 29 of http://www.stanford.edu/class/ee398a/handouts/lectures/01-EntropyLosslessCoding.pdf. See (Witten *et al*, 1999) and http://en.wikipedia.org/wiki/Golomb_coding, for similar discussion, though with slightly different notation. The primary reference is (Golomb, 1966).

Ideally, we'd like to do as little pruning as possible and we'd like to use as large a *P* as possible, subject to the memory allocation. We don't have a principled argument for how to balance Stolcke pruning losses with hashing losses; this can be arrived at empirically on an application-specific basis. For example, to fix the storage per *n*-gram at around 13 bits:

$$13 = \left\lceil \frac{1}{\log_e 2} + \log_2 \frac{1}{\lambda} \right\rceil$$

If we solve for λ, we obtain $\lambda \approx 1/20{,}0000$. In other words, set *P* to a prime near $20{,}000N$ and then do as much Stolcke pruning as necessary to meet the memory constraint. Then measure your application's accuracy, and adjust accordingly.

6.2 HashTBO Values and Alphas

There are *N* log likelihood values, one for each key. These *N* values are quantized into a small number of distinct bins. They are written out as a sequence of *N* Huffman codes. If there are Katz backoff alphas, then they are also written out as a sequence of *N* Huffman codes. (Unigrams and bigrams have alphas, but trigrams don't.)

6.3 HashTBO Lookup

The lookup process is given an *n*-gram, $w_{i-2} w_{i-1} w_i$, and is asked to estimate a log likelihood, $\log \Pr(w_i | w_{i-2}\, w_{i-1})$. Using the standard backoff model, this depends on the likelihoods for the unigrams, bigrams and trigrams, as well as the alphas.

The lookup routine not only determines if the *n*-gram is in the table, but also determines the offset within that table. Using that offset, we can find the appropriate log likelihood and alpha. Side tables are maintained to speed up random access.

7 ZipTBO Format

ZipTBO is a well-established representation of trigrams. Detailed descriptions can be found in (Clarkson and Rosenfeld 1997; Whittaker and Raj 2001).

ZipTBO consumes 8 bytes per unigram, 5 bytes per bigram and 2.5 bytes per trigram. In practice, this comes to about 4 bytes per n-gram on average.

Note that there are some important interactions between ZipTBO and Stolcke pruning. ZipTBO is relatively efficient for trigrams, compared to bigrams. Unfortunately, aggressive Stolcke pruning generates bigram-heavy models, which don't compress well with ZipTBO.

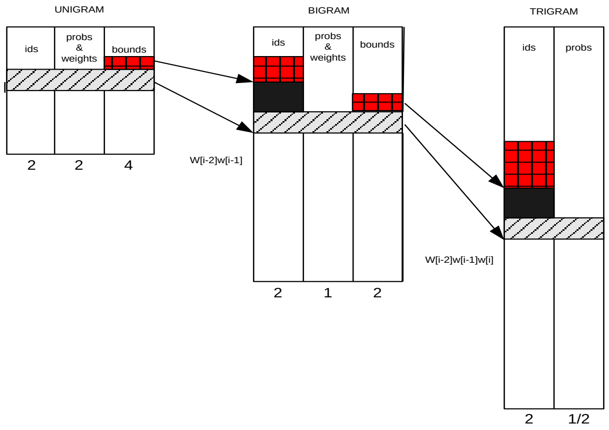


Figure 1. Tree structure of n-grams in ZipTBO format, following Whittaker and Ray (2001)

7.1 ZipTBO Keys

The tree structure of the trigram model is implemented using three arrays. As shown in Figure 1, from left to right, the first array (called *unigram array*) stores unigram nodes, each of which branches out into bigram nodes in the second array (*bigram array*). Each bigram node then branches out into trigram nodes in the third array (*trigram array*).

The length of the unigram array is determined by the vocabulary size (*V*). The lengths of the other two arrays depend on the number of bigrams and the number of trigrams, which depends on how aggressively they were pruned. (We do not prune unigrams.)

We store a 2-byte word id for each unigram, bigram and trigram.

The unigram nodes point to blocks of bigram nodes, and the bigram nodes point to blocks of trigram nodes. There are boundary symbols between blocks (denoted by the pointers in Figure 1). The boundary symbols consume 4 bytes for each unigram and 2 bytes for each bigram.

In each block, nodes are sorted by their word ids. Blocks are consecutive, so the boundary value of an $n-1$-gram node together with the boundary value of its previous $n-1$-gram node specifies, in the n-gram array, the location of the block containing all its child nodes. To locate a particular child node, a binary search of word ids is performed within the block.

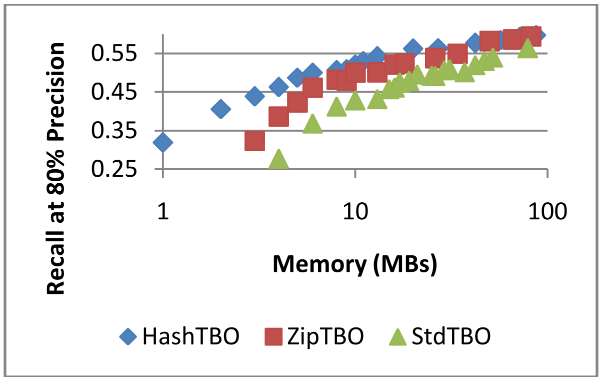

Figure 2. When there is plenty of memory, performance (recall @ 80% precision) asymptotes to the performance of baseline system with no compression (StdTBO). When memory is tight, HashTBO >> ZipTBO >> StdTBO.

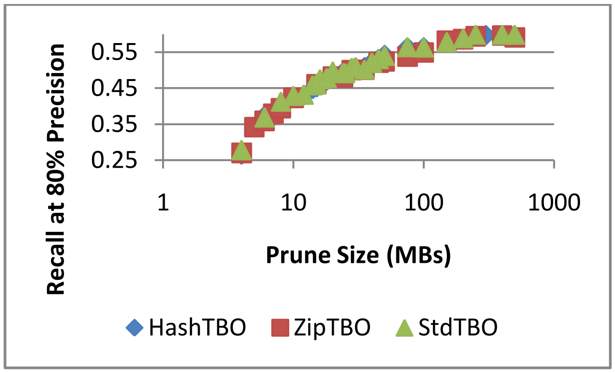

Figure 3. The differences between the methods in Figure 2 vanish if we adjust for prune size.

7.2 ZipTBO Values and Alphas

Like HashTBO, the log likelihood values and backoff alphas are quantized to a small number of quantization levels (256 levels for unigrams and 16 levels for bigrams and trigrams). Unigrams use a full byte for the log likelihoods, plus another full byte for the alphas. Bigrams use a half byte for the log likelihood, plus another half byte for the alphas. Trigrams use a half byte for the log likelihood. (There are no alphas for trigrams.)

7.3 ZipTBO Bottom Line

1. 8 bytes for each unigram:
   a. 2 bytes for a word id +
   b. 4 bytes for two boundary symbols +
   c. 1 byte for a log likelihood +
   d. 1 byte for an alpha
2. 5 bytes for each bigram:
   a. 2 bytes for a word id +
   b. 2 bytes for a boundary symbol +
   c. ½ bytes for a log likelihood +
   d. ½ bytes for an alpha
3. 2.5 bytes for each trigram:
   a. 2 bytes for a word id +
   b. ½ bytes for a log likelihood

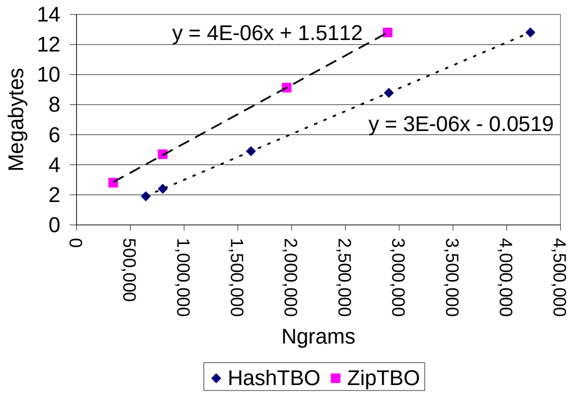

Figure 4. On average, HashTBO consumes about 3 bytes per n-gram, whereas ZipTBO consumes 4.

8 Evaluation

We normally think of trigram language models as memory hogs, but Figure 2 shows that trigrams can be squeezed down to a megabyte in a pinch. Of course, more memory is always better, but it is surprising how much can be done (27% recall at 80% precision) with so little memory.

Given a fixed memory budget, HashTBO outperforms ZipTBO which outperforms StdTBO, a baseline system with no compression. Compression matters more when memory is tight. The gap between methods is more noticeable at the low end (under 10 megabytes) and less noticeable at the high end (over 100 megabytes), where both methods asymptote to the performance of the StdTBO baseline.

All methods start with Stolcke pruning. Figure 3 shows that the losses are largely due to pruning.

All three methods perform about equally well, assuming the same amount of pruning.

The difference is that HashTBO can store more *n*-grams in the same memory and therefore it doesn't have to do as much pruning. Figure 4 shows that HashTBO consumes 3 bytes per *n*-gram whereas ZipTBO consumes 4.

Figure 4 combines unigrams, bigrams and trigrams into a single *n*-gram variable. Figure 5 drills down into this variable, distinguishing bigrams from trigrams. The axes here have been reversed so we can see that HashTBO can store more of both kinds in less space. Note that both HashTBO lines are above both ZipTBO lines.

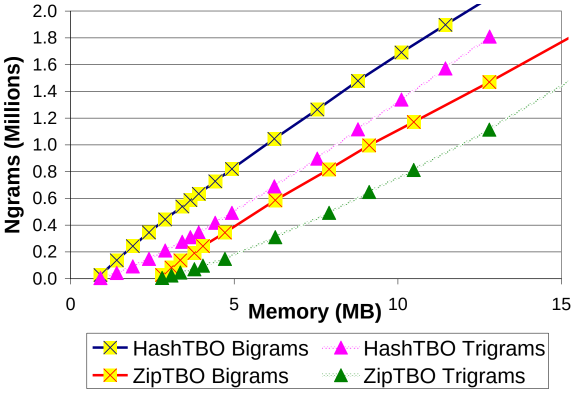

Figure 5. HashTBO stores more bigrams and trigrams than ZipTBO in less space.

In addition, note that both bigram lines are above both trigram lines (triangles). Aggressively pruned models have more bigrams than trigrams!

Linear regression on this data shows that HashTBO is no better than ZipTBO on trigrams (with the particular settings that we used), but there is a big difference on bigrams. The regressions below model *M* (memory in bytes) as a function of *bi* and *tri*, the number of bigrams and trigrams, respectively. (Unigrams are modeled as part of the intercept since all models have the same number of unigrams.)

$$M_{HashTBO} = 0.8 + 3.4bi + 2.6tri$$
$$M_{ZipTBO} = 2.6 + 4.9bi + 2.6tri$$

As a sanity check, it is reassuring that ZipTBO's coefficients of 4.9 and 2.6 are close to the true values of 5 bytes per bigram and 2.5 bytes per trigram, as reported in Section 7.3.

According to the regression, HashTBO is no better than ZipTBO for trigrams. Both models use roughly 2.6 bytes per trigram. When trigram models have relatively few trigrams, the other coefficients matter. HashTBO uses less space for bigrams (3.4 bytes/bigram << 4.9 bytes/bigram) and it has a better intercept (0.8 << 2.6).

We recommend HashTBO if space is so tight that it dominates other concerns. However, if there is plenty of space, or time is an issue, then the tradeoffs work out differently. Figure 6 shows that ZipTBO is an order of magnitude faster than HashTBO. The times are reported in microseconds per n-gram lookup on a dual Xeon PC with a 3.6 ghz clock and plenty of RAM (4GB). These times were averaged over a test set of 4 million lookups. The test process uses a cache. Turning off the cache increases the difference in lookup times.

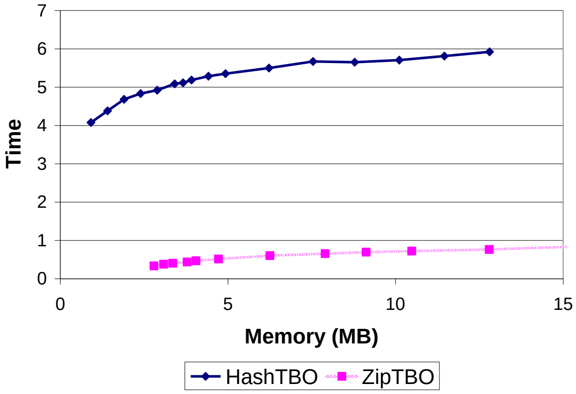

Figure 6. HashTBO is slower than ZipTBO.

9 Conclusion

Trigram language models were compressed using HashTBO, a Golomb coding method inspired by McIlroy's original spell program for Unix. McIlroy used the method to compress a dictionary of 32,000 words into a PDP-11 address space of 64k bytes. That is just 2 bytes per word!

We started with a large corpus of 6 billion words of English. With HashTBO, we could compress the trigram language model into just a couple of megabytes using about 3 bytes per n-gram (compared to 4 bytes per n-gram for the ZipTBO baseline). The proposed HashTBO method is not fast, and it is not accurate (not lossless), but it is hard to beat if space is tight, which was the case for the contextual speller in Microsoft Office 2007.

Acknowledgments

We would like to thank Dong-Hui Zhang for his contributions to ZipTBO.

Abstract

In morphologically rich languages, should morphological and syntactic disambiguation be treated sequentially or as a single problem? We describe several efficient, probabilistically-interpretable ways to apply **joint inference** to morphological and syntactic disambiguation using **lattice parsing**. Joint inference is shown to compare favorably to pipeline parsing methods across a variety of component models. State-of-the-art performance on Hebrew Treebank parsing is demonstrated using the new method. The benefits of joint inference are modest with the current component models, but appear to increase as components themselves improve.

1 Introduction

As the field of statistical NLP expands to handle more languages and domains, models appropriate for standard benchmark tasks do not always work well in new situations. Take, for example, parsing the *Wall Street Journal* Penn Treebank, a long-standing task for which highly accurate context-free models stabilized by the year 2000 (Collins, 1999; Charniak, 2000). On this task, the Collins model achieves 90% F_1-accuracy. Extended for new languages by Bikel (2004), it achieves only 75% on Arabic and 72% on Hebrew.[1]

It should come as no surprise that Semitic parsing lags behind English. The Collins model was carefully designed and tuned for *WSJ* English. Many of the features in the model depend on English syntax or Penn Treebank annotation conventions. Inherent in its crafting is the assumption that a million words of training text are available. Finally, for English, it need not handle morphological ambiguity.

Indeed, the figures cited above for Arabic and Hebrew are achieved using *gold-standard* morphological disambiguation and part-of-speech tagging. Given only surface *words*, Arabic performance drops by 1.5 F_1 points. The Hebrew Treebank (unlike Arabic) is built over *morphemes*, a convention we view as sensible, though it complicates parsing.

This paper considers parsing for *morphologically rich* languages, with Hebrew as a test case. Morphology and syntax are two levels of linguistic description that interact. This interaction, we argue, can affect disambiguation, so we explore here the matter of joint disambiguation. This involves the comparison of a **pipeline** (where morphology is inferred first and syntactic parsing follows) with **joint inference**. We present a generalization of the two, and show new ways to do joint inference for this task that does not involve a computational blow-up.

The paper is organized as follows. §2 describes the state of the art in NLP for Hebrew and some phenomena it exhibits that motivate joint inference for morphology and syntax. §3 describes our approach to joint inference using **lattice parsing**, and gives three variants of weighted lattice parsing with their probabilistic interpretations. The different factor models and their stand-alone performance are given in §4. §5 presents experiments on Hebrew parsing and explores the benefits of joint inference.

2 Background

In this section we discuss prior work on statistical morphological and syntactic processing of Hebrew and motivate the joint approach.

2.1 NLP for Modern Hebrew

Wintner (2004) reviews work in Hebrew NLP, emphasizing that the challenges stem from the writing system, rich morphology, unique word formation process of roots and patterns, and relative lack of annotated corpora.

We know of no publicly available statistical parser designed specifically for Hebrew. Sima'an et al.

* The authors acknowledge helpful feedback from the anonymous reviewers, Sharon Goldwater, Rebecca Hwa, Alon Lavie, and Shuly Wintner.

[1] Compared to the Penn Treebank, the Arabic Treebank (Maamouri et al., 2004) has 60% as many word tokens, and the Hebrew Treebank (Sima'an et al., 2001) has 6%.

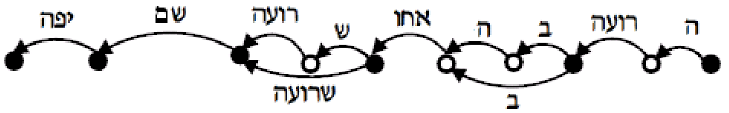

Figure 1: (a.) A sentence in Hebrew (to be read right to left), with (b.) one morphological analysis, (c.) English glosses, and (d.) natural translation; and (e.) a different morphological analysis, (f.) English glosses, and (g.) less natural translation. (h.) shows a morphological "sausage" lattice that encodes the morpheme-sequence analyses $L(\vec{x})$ possible for a shortened sentence (unmodified "meadow"). Shaded states are word boundaries, white states are intra-word morpheme boundaries; in practice we add POS tags to the arcs, to permit disambiguation. According to both native speakers we polled, both interpretations are grammatical—note the long-distance agreement required for grammaticality.

(2001) built a Hebrew Treebank of 88,747 words (4,783 sentences) and parsed it using a probabilistic model. However, they assumed that the input to the parser was already (perfectly) morphologically disambiguated. This assumption is very common in multilingual parsing (see, for example, Cowan et al., 2005, and Buchholz et al., 2006).

Until recently, the NLP literature on morphological processing was dominated by the largely non-probabilistic application of finite-state transducers (Kaplan and Kay, 1981; Koskenniemi, 1983; Beesley and Karttunen, 2003) and the largely unsupervised discovery of morphological patterns in text (Goldsmith, 2001; Wicentowski, 2002); Hebrew morphology receives special attention in Levinger et al. (1995), Daya et al. (2004), and Adler and Elhadad (2006). Lately a few supervised *disambiguation* methods have come about, including hidden Markov models (Hakkani-Tür et al., 2000; Hajič et al., 2001), conditional random fields (Kudo et al., 2004; Smith et al., 2005b), and local support vector machines (Habash and Rambow, 2005). There are also morphological disambiguators designed specifically for Hebrew (Segal, 2000; Bar-Haim et al., 2005).

2.2 Why Joint Inference?

In NLP, the separation of syntax and morphology is understandable when the latter is impoverished, as in English. When both involve high levels of ambiguity, this separation becomes harder to justify, as argued by Tsarfaty (2006). To our knowledge, that is the only study to move toward joint inference of syntax and morphology, presenting joint models and testing approximation of these models with two parsers: one a pipeline (segmentation → tagging → parsing), the other involved joint inference of segmentation and tagging, with the result piped to the parser. The latter was slightly more accurate. Tsarfaty discussed but did not carry out joint inference.

In a morphologically rich language, the different morphemes that make up a word can play a variety of different syntactic roles. A reasonable linguistic analysis might not make such morphemes immediate sisters in the tree. Indeed, the convention of the Hebrew Treebank is to place *morphemes* (rather than words) at the leaves of the parse tree, allowing morphemes of a word to attach to different nonterminal parents.[2]

Generating parse trees over morphemes requires the availability of morphological information when parsing. Because this analysis is not in general reducible to sequence labeling (tagging), the problem is different from POS tagging. Figure 1 gives an

[2] The Arabic Treebank, by contrast, annotates words morphologically but keeps the morphemes together as a single node tagged with a POS sequence. In Bikel's Arabic parser, complex POS tags are projected to a small atomic set; it is unclear how much information is lost.

example from Hebrew that illustrates the interaction between morphology and syntax. In this example, we show two interpretations of the surface text, with the first being a more common natural analysis for the sentence. The first and third-to-last words' analyses depend on each other if the resulting analysis is to be the more natural one: for this analysis the first seven words have to be a noun phrase, while for the less common analysis ("lying there nicely") only the first six words compose a noun phrase, with the last two words composing a verb phrase. Consistency depends on a long-distance dependency that a finite-state morphology model cannot capture, but a model that involves syntactic information can. Disambiguating the syntax aids in disambiguating the morphology, suggesting that a joint model will perform both more accurately.

In sum, joint inference of morphology and syntax is expected to allow decisions of both kinds to influence each other, enforce adherence to constraints at both levels, and to diminish the propagation of errors inherent in pipelines.

3 Joint Inference of Morphology and Syntax

We now formalize the problem and supply the necessary framework for performing joint morphological disambiguation and syntactic parsing.

3.1 Notation and Morphological Sausages

Let $\mathcal{X}$ be the language's word vocabulary and $\mathcal{M}$ be its morpheme inventory. The set of valid analyses for a surface word is defined using a morphological lexicon L, which defines $L(x) \subseteq \mathcal{M}^+$. $L(\vec{x}) \subseteq (\mathcal{M}^+)^+$ (sequence of sequences) is the set of whole-sentence analyses for sentence $\vec{x} = \langle x_1, x_2, ..., x_n \rangle$, produced by concatenating elements of $L(x_i)$ in order. $L(\vec{x})$ can be represented as an acyclic lattice with a "sausage" shape familiar from speech recognition (Mangu et al., 1999) and machine translation (Lavie et al., 2004). Fig. 1h shows a sausage lattice for a sentence in Hebrew. We use $\vec{m}$ to denote an element of $L(\vec{x})$ and $\vec{m}_i$ to denote an element of $L(x_i)$; in general, $\vec{m} = \langle \vec{m}_1, \vec{m}_2, ..., \vec{m}_n \rangle$.

We are interested in a function $f : \mathcal{X}^+ \rightarrow (\mathcal{M}^+)^+ \times \mathcal{T}$, where $\mathcal{T}$ is the set of syntactic trees for the language. f can be viewed as a structured classifier. We use $D_G(\vec{m}) \subseteq \mathcal{T}$ to denote the set of valid trees under a grammar G (here, a PCFG with terminal alphabet $\mathcal{M}$) for morpheme sequence $\vec{m}$. To be precise, $f(\vec{x})$ selects a mutually consistent morphological and syntactic analysis from

$$\text{GEN}(\vec{x}) = \{\langle \vec{m}, \tau \rangle \mid \vec{m} \in L(\vec{x}), \tau \in D_G(\vec{m})\}$$

3.2 Product of Experts

Our mapping $f(\vec{x})$ is based on a joint probability model $p(\tau, \vec{m} \mid \vec{x})$ which combines two probability models $p_G(\tau, \vec{m})$ (a PCFG built on the grammar G) and $p_L(\vec{m} \mid \vec{x})$ (a morphological disambiguation model built on the lexicon L). Factoring the joint model into sub-models simplifies **training**, since we can train each model separately, and **inference** (parsing), as we will see later in this section. Factored estimation has been quite popular in NLP of late (Klein and Manning, 2003b; Smith and Smith, 2004; Smith et al., 2005a, *inter alia*).

The most obvious joint parser uses p_G as a conditional model over trees given morphemes and maximizes the joint likelihood:

$$\begin{aligned} & f_{\text{lik}}(\vec{x}) \\ & = \operatorname*{argmax}_{\langle \vec{m}, \tau \rangle \in \text{GEN}(\vec{x})} p_G(\tau \mid \vec{m}) \cdot p_L(\vec{m} \mid \vec{x}) \qquad (1) \\ & = \operatorname*{argmax}_{\langle \vec{m}, \tau \rangle \in \text{GEN}(\vec{x})} \frac{p_G(\tau, \vec{m})}{\sum_{\tau'} p_G(\tau', \vec{m})} \cdot \frac{p_L(\vec{m}, \vec{x})}{\sum_{\vec{m}'} p_L(\vec{m}', \vec{x})} \end{aligned}$$

This is not straightforward, because it involves summing up the trees for each $\vec{m}$ to compute $p_G(\vec{m})$, which calls for the $O(|\vec{m}|^3)$-Inside algorithm to be called on each $\vec{m}$. Instead, we use the joint, $p_G(\tau, \vec{m})$, which, strictly speaking, makes the model deficient ("leaky"), but permits a dynamic programming solution.

Our models will be parametrized using either unnormalized weights (a log-linear model) or multinomial distributions. Either way, both models define *scores* over parts of analyses, and it may be advantageous to give one model relatively greater strength, especially since we often ignore constant normalizing factors. This is known as a **product of experts** (Hinton, 1999), where a new combined distribution over events is defined by multiplying component distributions together and renormalizing. In the present setting, for some value $\alpha \geq 0$,

$$f_{\text{poe},\alpha}(\vec{x}) = \underset{\langle \vec{m},\tau\rangle \in \text{GEN}(\vec{x})}{\text{argmax}} \frac{p_G(\tau, \vec{m}) \cdot p_L(\vec{m} \mid \vec{x})^\alpha}{Z(\vec{x}, \alpha)} \tag{2}$$

where $Z(\vec{x}, \alpha)$ need not be computed (since it is a constant in $\vec{m}$ and τ). α tunes the relative weight of the morphology model with respect to the parsing model. The higher α is, the more we trust the morphology model over the parser to correctly disambiguate the sentence. We might trust one model more than the other for a variety of reasons: it could be more robustly or discriminatively estimated, or it could be known to come from a more appropriate family.

This formulation also generalizes two more naïve parsing methods. If $\alpha = 0$, the morphology is modeled only through the PCFG and p_L is ignored except as a constraint on which analyses $L(\vec{x})$ are allowed (i.e., on the definition of the set $\text{GEN}(\vec{x})$). At the other extreme, as $\alpha \to +\infty$, p_L becomes more important. Because p_L does not predict trees, p_G still "gets to choose" the syntax tree, but in the limit it must find a tree for $\text{argmax}_{\vec{m} \in L(\vec{x})} p_L(\vec{m} \mid \vec{x})$. This is effectively the morphology-first pipeline.[3]

3.3 Parsing Algorithms

To parse, we apply a dynamic programming algorithm in the $\langle$max, +$\rangle$ semiring to solve the $f_{\text{poe},\alpha}$ problem shown in Eq. 4. If p_L is a unigram-factored model, such that for some single-word morphological model υ we have

$$p_L(\vec{m} \mid \vec{x}) = \prod_{i=1}^n \upsilon(\vec{m}_i \mid x_i) \tag{3}$$

then we can implement morpho-syntactic parsing by *weighting* the sausage lattice. Let the weight of each arc that starts an analysis $\vec{m}_i \in L(x_i)$ be equal to $\log \upsilon(\vec{m}_i \mid x_i)$, and let other arcs have weight 0. In the parsing algorithm, the weight on an arc is summed in when the arc is first used to build a constituent.

In general, we would like to define a joint model that assigns (unnormalized) probabilities to elements of $\text{GEN}(\vec{x})$. If p_G is a PCFG and p_L can be described as a weighted finite-state transducer, then this joint model is their *weighted composition*, which is a weighted CFG; call the composed grammar I and its (unnormalized) distribution p_I. Compared to G, I will have many more nonterminals if p_L has a Markov order greater than 0 (unigram, as above). Because parsing runtime depends heavily on the grammar constant (at best, quadratic in the number of nonterminals), parsing with p_I is not computationally attractive.[4] $f_{\text{poe},\alpha}$ is not, then, a scalable solution when we wish to use a morphology model p_L that can make interdependent decisions about different words in $\vec{x}$ in context. We propose two new, efficient dynamic programming solutions for joint parsing.

In the first, we approximate the distribution $p_L(\vec{M} \mid \vec{x})$ using a unigram-factored model of the form in Eq. 3:

$$p'_L(\vec{m} \mid \vec{x}) = \prod_{i=1}^n \underbrace{p_L(\vec{M}_i = \vec{m}_i \mid \vec{x})}_{\text{posterior, depends on all of } \vec{x}} \tag{7}$$

Similar methods were applied by Matsuzaki et al. (2005) and Petrov and Klein (2007) for parsing under a PCFG with nonterminals with latent annotations. Their approach was variational, approximating the true posterior over coarse parses using a sentence-specific PCFG on the coarse nonterminals, created directly out of the true fine-grained PCFG. In our case, we approximate the full distribution over morphological analyses for the sentence by a simpler, sentence-specific unigram model that assumes each word's analysis is to be chosen independently of the others. Note that our *model* (p_L) does not make such an assumption, only the approximate model p'_L does, and the approximation is per-sentence. The idea resembles a mean-field variational approximation for graphical models. Turning to implementation, we can solve for $p_L(\vec{m}_i \mid \vec{x})$ exactly using the forward-backward algorithm. We will call this method $f_{\text{vari},\alpha}$ (see Eq. 5).

A closely related method, applied by Goodman (1996) is called **minimum-risk** decoding. Goodman called it "maximum expected recall" when applying it to parsing. In the HMM community it

[3] There is a slight difference. If no parse tree exists for the p_L-best morphological analysis, then a less probable $\vec{m}$ may be chosen. So as $\alpha \to +\infty$, we can view $f_{\text{lik},\alpha}$ as finding the best *grammatical* $\vec{m}$ and its best tree—not exactly a pipeline.

[4] In prior work involving factored syntax models—lexicalized (Klein and Manning, 2003b) and bilingual (Smith and Smith, 2004)—$f_{\text{poe},1}$ was applied, and the asymptotic runtime went to $O(n^5)$ and $O(n^7)$.

$$f_{\text{poe},\alpha}(\vec{x}) = \operatorname*{argmax}_{\langle\vec{m},\tau\rangle\in\text{GEN}(\vec{x})} \log p_G(\tau,\vec{m}) + \alpha \log p_L(\vec{m} \mid \vec{x}) \quad (4)$$

$$f_{\text{vari},\alpha}(\vec{x}) = \operatorname*{argmax}_{\langle\vec{m},\tau\rangle\in\text{GEN}(\vec{x})} \log p_G(\tau,\vec{m}) + \alpha \textstyle\sum_{i=1}^{n} \log p_L(\vec{m}_i \mid \vec{x}) \quad (5)$$

$$f_{\text{risk},\alpha}(\vec{x}) = \operatorname*{argmax}_{\langle\vec{m},\tau\rangle\in\text{GEN}(\vec{x})} \log p_G(\tau,\vec{m}) + \alpha \textstyle\sum_{i=1}^{n} p_L(\vec{m}_i \mid \vec{x}) \quad (6)$$

is sometimes called "posterior decoding." Minimum risk decoding is attributable to Goel and Byrne (2000). Applied to a single model, it factors the parsing decision by penalizable errors, and chooses the solution that minimizes the risk (expected number of errors under the model). This factors into a sum of expectations, one per potential mistake. This method is expensive for parsing models (since it requires the Inside algorithm to compute expected recall mistakes), but entirely reasonable for sequence labeling models. The idea is to score each word-analysis $\vec{m}_i$ in the morphological lattice by the expected value (under p_L) that $\vec{m}_i$ is present in the final analysis $\vec{m}$. This is, of course $p_L(\vec{M}_i = \vec{m}_i \mid \vec{x})$, the same quantity computed for $f_{\text{vari},\alpha}$, except the score of a path in the lattice is now a *sum* of posteriors rather than a *product*. Our second approximate joint parser tries to maximize the *probability* of the parse (as before) and at the same time to minimize the *risk* of the morphological analysis. See $f_{\text{risk},\alpha}$ in Eq. 6; the only difference between $f_{\text{risk},\alpha}$ and $f_{\text{vari},\alpha}$ is whether posteriors are added ($f_{\text{risk},\alpha}$) or multiplied ($f_{\text{vari},\alpha}$).

To summarize this section, $f_{\text{vari},\alpha}$ and $f_{\text{risk},\alpha}$ are two approximations to the expensive-in-general $f_{\text{poe},\alpha}$ that boil down to parsing over weighted lattices. The only difference between them is how the lattice is weighted: using $\alpha \log p_L(\vec{m}_i \mid \vec{x})$ for $f_{\text{vari},\alpha}$ or using $\alpha p_L(\vec{m}_i \mid \vec{x})$ for $f_{\text{risk},\alpha}$.[5] In case of a unigram p_L, $f_{\text{poe},\alpha}$ is equivalent to $f_{\text{vari},\alpha}$; otherwise $f_{\text{poe},\alpha}$ is likely to be too expensive.

3.4 Lattice Parsing

To parse the weighted lattices using $f_{\text{vari},\alpha}$ and $f_{\text{risk},\alpha}$ in the previous section, we use *lattice parsing*. Lattice parsing is a straightforward generalization of string parsing that indexes constituents by states in the lattice rather than word interstices. At parsing time, a ⟨max, +⟩ lattice parser finds the best combined parse tree and path through the lattice. Importantly, the data structures that are used in chart parsing need not change in order to accommodate lattices. The generalization over classic Earley or CKY parsing is simple: keep in the parsing chart constituents created over a pair of start state and end state (instead of start position and end position), and (if desired) factor in weights on lattice arcs; see Hall (2005).

4 Factored Models

A fair comparison of joint and pipeline parsing must make some attempt to control for the component models. We describe here two PCFGs we used for $p_G(\tau, \vec{m})$ and two finite-state morphological models we used for $p_L(\vec{m} \mid \vec{x})$. We show how these models perform in stand-alone evaluations. For all experiments, we used the Hebrew Treebank (Sima'an et al., 2001). After removing traces and removing functional information from the nonterminals, we had 3,770 sentences in the training set, 371 sentences in the development set (used primarily to select the value of α) and 370 sentences in the test set.

4.1 Syntax Model

Our first syntax model is an unbinarized PCFG trained using relative frequencies. Preterminal (POS tag → morpheme) rules are smoothed using backoff to a model that predicts the morpheme length and letter sequence. The PCFG is not binarized. This grammar is remarkably good, given the limited effort that went into it. The rules in the training set had **high coverage** with respect to the development set: an oracle experiment in which we maximized the number of recovered gold-standard constituents (on the development set) gave F_1 accuracy of 93.7%. In fact, its accuracy supersedes

[5] Until now, we have talked about weighting *word analyses*, which may cover several arcs, rather than arcs. In practice we apply the weight to the first arc of a word analysis, and weight the remaining arcs of that analysis with 0 (no cost or benefit), giving the desired effect.

more complex, lexicalized, models: given gold-standard morphology, it achieves 81.2% (compared to 72.0% by Bikel's parser, with head rules specified by a native speaker). This is probably attributable to the dataset's size, which makes training with highly-parameterized lexicalized models precarious and prone to overfitting. With first-order **vertical markovization** (i.e., annotating each nonterminal with its parent as in Johnson, 1998), accuracy is also at 81.2%. Tuning the horizontal markovization of the grammar rules (Klein and Manning, 2003a) had a small, adverse effect on this dataset.

Since the PCFG model was relatively successful compared to lexicalized models, and is faster to run, we decided to use a vanilla PCFG, denoted G_{van}, and a parent-annotated version of that PCFG (Johnson, 1998), denoted $G_{\text{v}=2}$.

4.2 Morphology Model

Both of our morphology models use the same morphological lexicon L, which we describe first.

4.2.1 Morphological Lexicon

In this work, a morphological analysis of a word is a sequence of morphemes, possibly with a tag for each morpheme. There are several available analyzers for Hebrew, including Yona and Wintner (2005) and Segal (2000). We use instead an empirically-constructed generative lexicon that has the advantage of matching the Treebank data and conventions. If the Treebank is enriched, this would then directly benefit the lexicon and our models.

Starting with the training data from the Hebrew Treebank, we first create a set of **prefixes** $\mathcal{M}_{\text{p}} \subset \mathcal{M}$; this set includes any morpheme seen in a non-final position within any word. We also create a set of **stems** $\mathcal{M}_{\text{s}} \subset \mathcal{M}$ that includes any morpheme seen in a final position in a word. This effectively captures the morphological analysis convention in the Hebrew Treebank, where a stem is prefixed by a relatively dominant low-entropy sequence of 0–5 prefix morphemes. For example, *MHKLB* ("from the dog") is analyzed as *M+H+KLB* with prefixes *M* ("from") and *H* ("the") and *KLB* ("dog") is the stem. In practice, $|\mathcal{M}_{\text{p}}| = 124$ (including some conventions for numerals) and $|\mathcal{M}_{\text{s}}| = 13{,}588$. The morphological lexicon is then defined as any analysis given $\mathcal{M}_{\text{p}}$ and $\mathcal{M}_{\text{s}}$:

$$\begin{aligned} L(x) &= \{m_1^k \in \mathcal{M}_{\text{p}}^* \times \mathcal{M}_{\text{s}} \mid \text{concat}(m_1^k) = x)\} \\ &\quad \cup \{m_1^k \mid \text{count}(m_1^k, x) \geq 1\} \end{aligned} \tag{9}$$

where m_1^k denotes $\langle m_1, ..., m_k \rangle$ and $\text{count}(m_1^k, x)$ denotes the number of occurrences of x disambiguated as m_1^k in the training set. Note that $L(x)$ also includes any analysis of x observed in the training data. This permits the memorization of any observed analysis that is more involved than simple segmentation (4% of word tokens in the training set; e.g., *LXDR* ("to the room") is analyzed as *L+H+XDR*). This will have an effect on evaluation (see §5.1). On the development data, L has 98.6% coverage.

4.2.2 Unigram Baseline

The baseline morphology model, p_L^{uni}, first defines a joint distribution following Eq. 8. The word model factors out when we conditionalize to form $p_L^{\text{uni}}(\langle m_1, ..., m_k \rangle \mid x)$. The prefix sequence model is multinomial estimated by MLE. The stem model (conditioned on the prefix sequence) is smoothed to permit *any* stem that is a sequence of Hebrew characters. On the development data, p_L^{uni} is 88.8% accurate (by word).

4.2.3 Conditional Random Field

The second morphology model, p_L^{crf}, which is based on the same morphological lexicon L, uses a second-order conditional random field (Lafferty et al., 2001) to disambiguate the full sentence by modeling local contexts (Kudo et al., 2004; Smith et al., 2005b). Space does not permit a full description; the model uses all the features of Smith et al. (2005b) except the "lemma" portion of the model, since the Hebrew Treebank does not provide lemmas. The weights are trained to maximize the probability of the correct path through the morphological lattice, conditioned on the lattice. This is therefore a **discriminative** model that defines $p_L(\vec{m} \mid \vec{x})$ directly, though we ignore the normalization factor in parsing.

Until now we have described p_L as a model of morphemes, but this CRF is trained to predict POS tags as well—we can either use the tags (i.e., label the morphological lattice with tag/morpheme pairs,

$$p_L^{\text{uni}}(\langle m_1, m_2, ..., m_k\rangle, x) = \underbrace{p(x \mid \langle m_1, m_2, ..., m_k\rangle)}_{\text{word}} \cdot \underbrace{p(m_k \mid \langle m_1, ..., m_{k-1}\rangle)}_{\text{stem}} \cdot \underbrace{p(\langle m_1, ..., m_{k-1}\rangle)}_{\text{prefix sequence}} \quad (8)$$

so that the lattice parser finds a parse that is consistent under both models), or sum the tags out and let the parser do the tagging. One subtlety is the tagging of words not seen in the training data; for such words an unsegmented hypothesis with tag UNKNOWN is included in the lattice and may therefore be selected by the CRF. On the development data, p_L^{crf} is 89.8% accurate on morphology, with 74.9% fine-grained POS-tagging F_1-accuracy (see §5.1).

Note on generative and discriminative models. The reader may be skeptical of our choice to combine a generative PCFG with a discrimative CRF. We point out that both are used to define conditional distributions over desired "output" structures given "input" sequences. Notwithstanding the fact that the factors can be *estimated* in very different ways, our combination in an exact or approximate product-of-experts is a reasonable and principled approach.

5 Experiments

In this section we evaluate parsing performance, but an evaluation issue is resolved first.

5.1 Evaluation Measures

The "Parseval" measures (Black et al., 1991) are used to evaluate a parser's phrase-structure trees against a gold standard. They compute precision and recall of constituents, each indexed by a label and two endpoints. As pointed out by Tsarfaty (2006), joint parsing of morphology and syntax renders this indexing inappropriate, since it assumes the yields of the trees are identical—that assumption is violated if there are any errors in the hypothesized $\vec{m}$. Tsarfaty (2006) instead indexed by non-whitespace *character* positions, to deal with segmentation mismatches. In general (and in this work) that is still insufficient, since $L(\vec{x})$ may include $\vec{m}$ that are not simply segmentations of $\vec{x}$ (see §4.2.1).

Roark et al. (2006) propose an evaluation metric for comparing a parse tree over a sentence generated by a speech recognizer to a gold-standard parse. As in our case, the hypothesized tree could have a different yield than the original gold-standard parse tree, because of errors made by the speech recognizer. The metric is based on an alignment between the hypothesized sentence and the gold-standard sentence. We used a similar evaluation metric, which takes into account the information about parallel word boundaries as well, a piece of information that does not appear naturally in speech recognition. Given the correct $\vec{m}^*$ and the hypothesis $\hat{\vec{m}}$, we use dynamic programming to find an optimal many-to-many monotonic alignment between the atomic morphemes in the two sequences. The algorithm penalizes each violation (by a morpheme) of a one-to-one correspondence,[6] and each character edit required to transform one side of a correspondence into the other (without whitespace). Word boundaries are (here) known and included as index positions. In the case where $\hat{\vec{m}} = \vec{m}^*$ (or equal up to whitespace) the method is identical to Parseval (and also to Tsarfaty, 2006). POS tag accuracy is evaluated the same way, for the same reasons; we report F_1-accuracy for tagging and parsing.

5.2 Experimental Comparison

In our experiment we vary four settings:

- Decoding algorithm: $f_{\text{poe},\alpha}$, $f_{\text{risk},\alpha}$, or $f_{\text{vari},\alpha}$ (§3.3).
- Syntax model: G_{van} or $G_{\text{v=2}}$ (§4.1).
- Morphology model: p_L^{uni} or p_L^{crf} (§4.2). In the latter case, we can use the scores over morpheme sequences only (summing out tags before lattice parsing; denoted m.-p_L^{crf}) or the full model over morphemes and tags, denoted t.-p_L^{crf}.[7]
- α, the relative strength given to the morphology model (see §3). We tested values of α in $\{0, +\infty\} \cup \{10^q \mid q \in \{0, 1, ..., 16\}\}$. Recall that $\alpha = 0$ ignores the morphology model probabilities altogether (using an unweighted lattice),

[6] That is, in a correspondence of a morphemes in one string with b in the other, the penalty is $a + b - 2$, since the morpheme on each side is not in violation.

[7] One subtlety is that any arc with the UNKNOWN POS tag can be relabeled—to any other tag—by the syntax model, whose preterminal rules are smoothed. This was crucial for $\alpha = +\infty$ (pipeline) parsing with t.-p_L^{crf} as the morphology model, since the parser does not recognize UNKNOWN as a tag.

Table 1: Results of experiments on Hebrew (test data, max. length 40). This table shows the performance of **joint parsing** (finite α; left) and a **pipeline** ($\alpha \to +\infty$; right). Joint parsing with a non-unigram morphology model is too expensive (marked $*$). Morphological analysis accuracy (by word), fine-grained (full tags) and coarse-grained (only parts of speech) POS tagging accuracy (F_1), and generalized constituent accuracy (F_1) are reported; α was tuned for each of these separately. **Boldface** denotes that figures were significantly better than their counterparts in the same row, under a binomial sign test ($p < 0.05$). † marks the best overall accuracy and figures that are not significantly worse (binomial sign test, $p < 0.05$).

and as $\alpha \to +\infty$ a morphology-first pipeline is approached.

We measured four outcome values: segmentation accuracy (fraction of word tokens segmented correctly), fine- and coarse-grained tagging accuracy,[8] and parsing accuracy. For tagging and parsing, F_1-measures are given, according to the generalized evaluation measure described in §5.1.

5.3 Results

Tab. 1 compares parsing with tuned α values to the pipeline.

The best results were achieved using $f_{\text{vari},\alpha}$, using the CRF and joint disambiguation. Without the CRF (using p_L^{uni}), the difference between the decoding algorithms is less apparent, suggesting an interaction between the sophistication of the components and the best way to decode with them. These results suggest that $f_{\text{vari},\alpha}$, which permits p_L to "veto" any structure involving a morphological analysis for any word that is *a posteriori* unlikely (note that $\log p_L(\vec{m}_i \mid \vec{x})$ can be an arbitrarily large negative number), is beneficial as a "filter" on parses.[9] $f_{\text{risk},\alpha}$, on the other hand, is only allowed to give "bonuses" of up to α to each morphological analysis that p_L believes in; its influence is therefore weaker. This result is consistent with the findings of Petrov et al. (2007) for another approximate parsing task.

The advantage of the parent-annotated PCFG is also more apparent when the CRF is used for morphology, and when α is tuned. All other things equal, then, p_L^{crf} led to higher accuracy all around. Letting the CRF help predict the POS tags helped tagging accuracy but not parsing accuracy.

While the gains over the pipeline are modest, the segmentation, fine POS, and parsing accuracy scores achieved by joint disambiguation with $f_{\text{vari},\alpha}$ with the CRF are significantly better than any of the pipeline conditions.

Interestingly, if we had not tested with the CRF, we might have reached a very different conclusion about the usefulness of tuning α as opposed to a pipeline. With the unigram morphology model, joint parsing frequently *underperforms* the pipeline, sometimes even signficantly. The explanation, we

[8] Although the Hebrew Treebank is small, the size of its POS tagset is large (four times larger than the Penn Treebank), because the tags encode morphological features (gender, person, and number). These features have either been ignored in prior work or encoded differently. In order for our POS-tagging figures to be reasonably comparable to previous work, we include accuracy for coarse-grained tags (only the core part of speech) tags as well as the detailed Hebrew Treebank tags.

[9] Another way to describe this combination is to call it a product of $|\vec{x}|+1$ experts: one for the morphological analysis of each word, plus the grammar. The morphology experts (softly) veto any analysis that is dubious based on surface criteria, and the grammar (softly) vetoes less-grammatical parses.

parser	morph. model	syntax model	seg. acc	fine POS F_1	coarse POS F_1	parse F_1

Table 2: **Oracle** results of experiments on Hebrew (test data, max. length 40). This table shows the performance of morphological segmentation, part-of-speech tagging, coarse part-of-speech tagging and parsing when using an oracle to select the best α for each sentence. The notation and interpretation of the numbers are the same as in Tab. 1.

believe, has to do with the ability of the unigram model to estimate a good *distribution* over analyses. While the unigram model is nearly as good as the CRF at picking the right segmentation for a word, joint parsing demands much more. In case the best segmentation does not lead to a grammatical morpheme sequence (under the syntax model), the morphology model needs to be able to give relative strengths to the alternatives. The unigram model is less able to do this, because it ignores the context of the word, and so the benefit of joint parsing is lost.

Most commonly the tuned value of α is around 10 (not shown, to preserve clarity). Because of ignored normalization constants, this does *not* mean that morphology is “10× more important than syntax,” but it *does* mean that, for a particular p_L and p_G, tuning their relative importance in decoding can improve accuracy. In Tab. 2 we show how performance would improve if the oracle value of α was selected for each test-set *sentence*; this further highlights the potential impact of perfecting the tradeoff between models. Of course, selecting α automatically at test-time, per sentence, is an open problem.

To our knowledge, the parsers we have described represent the state-of-the-art in Modern Hebrew parsing. The closest result is Tsarfaty (2006), which we have not directly replicated. Tsarfaty’s model is essentially a pipeline application of $f_{\text{poe},\infty}$ with a grammar like $p_{G_{\text{van}}}$. Her work focused more on the interplay between the segmentation and POS tagging models and the amount of information passed to the parser. Some key differences preclude direct comparison: we modeled fine-grained tags (though we report both kinds of tagging accurcy), we employed a richer morphological lexicon (permitting analyses that are not just segmentation), and a different training/test split and length filter (we used longer sentences). Nonetheless, our conclusions support the argument in Tsarfaty (2006) for more integrated parsing methods.

We conclude that tuning the relative importance of the two models—rather than pipelining to give one infinitely more importance—can provide an improvement on segmentation, tagging, and parsing accuracy. This suggests that future parsing efforts for languages with rich morphology might continue to assume separately-trained (and separately-improved) morphology and syntax components, which would stand to gain from joint decoding. In our experiments, better morphological disambiguation was crucial to getting any benefit from joint decoding. Our result also suggests that exploring new, fully-integrated models (and training methods for them) may be advantageous.

6 Conclusion

We showed that joint morpho-syntactic parsing can improve the accuracy of both kinds of disambiguation. Several efficient parsing methods were presented, using factored state-of-the-art morphology and syntax models for the language under consideration. We demonstrated state-of-the-art performance on and consistent improvements across many settings for Modern Hebrew, a morphologically-rich language with a relatively small treebank.

Abstract

This paper proposes a new bootstrapping approach to unsupervised part-of-speech induction. In comparison to previous bootstrapping algorithms developed for this problem, our approach aims to improve the quality of the seed clusters by employing seed words that are both distributionally and morphologically reliable. In particular, we present a novel method for combining morphological and distributional information for seed selection. Experimental results demonstrate that our approach works well for English and Bengali, thus providing suggestive evidence that it is applicable to both morphologically impoverished languages and highly inflectional languages.

1 Introduction

The availability of a high-quality lexicon is crucial to the development of fundamental text-processing components such as part-of-speech (POS) taggers and syntactic parsers. While hand-crafted lexicons are readily available for resource-rich languages such as English, the same is not true for *resource-scarce* languages. Unfortunately, manually constructing a lexicon requires a lot of linguistic expertise, and is practically infeasible for highly inflectional and agglutinative languages, which contain a very large number of lexical items. Given the scarcity of annotated data for acquiring the lexicon in a supervised manner, researchers have instead investigated *unsupervised* POS induction techniques for automating the lexicon construction process. In essence, the goal of unsupervised POS induction is to learn the set of possible POS tags for each lexical item from an unannotated corpus.

The most common approach to unsupervised POS induction to date has been motivated by Harris's (1954) distributional hypothesis: words with similar co-occurrence patterns should have similar syntactic behavior. More specifically, unsupervised POS induction algorithms typically operate by (1) representing each *target* word (i.e., a word to be tagged with its POS) as a *context* vector that encodes its left and right context, (2) clustering distributionally similar words, and (3) manually labeling each cluster with a POS tag by inspecting the members of the cluster.

This *distributional* approach works under the assumption that the context vector of each word encodes sufficient information for enabling accurate word clustering. However, many words are *distributionally unreliable*: due to data sparseness, they occur infrequently and hence their context vectors do not capture reliable statistical information. To overcome this problem, Clark (2000) proposes a bootstrapping approach, in which he (1) clusters the most distributionally reliable words, and then (2) incrementally augments each cluster with words that are distributionally similar to those already in the cluster.

The goal of this paper is to propose a new bootstrapping approach to unsupervised POS induction that can operate in a resource-scarce setting. Most notably, our approach aims to improve the quality of the seed clusters by employing seed words that are both *distributionally* and *morphologically* reliable. In particular, we present a novel method for combining morphological and distributional information for seed selection. Furthermore, given our

Proceedings of the 2007 Joint Conference on Empirical Methods in Natural Language Processing and Computational Natural Language Learning, pp. 218–227, Prague, June 2007.

emphasis on resource-scarce languages, our approach does not rely on any language resources. In particular, the morphological information that it exploits is provided by an unsupervised morphological analyzer.

It is perhaps not immediately clear why morphological information would play a crucial role in the induction process, especially since the distributional approach has achieved considerable success for English POS induction (see Lamb (1961), Schütze (1995) and Clark (2000)). To understand the role and significance of morphology, it is important to first understand why the distributional approach works well for English. Recall from the above that the distributional approach assumes that the information encoded in the context vector of each word, which typically consists of the 250 most frequent words of a given language, is sufficient for accurately clustering the words. This approach works well for English because the most frequent English words are composed primarily of closed-class words such as "to" and "is", which provide strong clues to the POS of the target word. However, this assumption is not necessarily valid for fairly free word order and highly inflectional languages such as Bengali. The reason is that (1) co-occurrence statistics collected from free word order languages are not as reliable as those from fixed word order languages; and (2) many of the closed-class words that appear in the context vector for English words are realized as inflections in Bengali. The absence of these highly informative words implies that the context vectors may no longer capture sufficient information for accurately clustering Bengali words, and hence the use of morphological information becomes particularly important for unsupervised POS induction for these inflectional languages.

We will focus primarily on labeling *open-class* words with their POS tags. Our decision is motivated by the fact that closed-class words generally comprise a small percentage of the lexical items of a language. In Bengali, the percentage of closed-class words is even smaller than that in English: as mentioned before, many closed-class words in English are realized as suffixes in Bengali.

Although our attempt to incorporate morphological information into the distributional POS induction framework was originally motivated by inflectional languages, experimental results show that our approach works well for both English and Bengali, suggesting its applicability to both morphologically impoverished languages and highly inflectional languages. Owing to the lack of publicly available resources for Bengali, we manually created a 5000-word Bengali lexicon for evaluation purposes. Hence, one contribution of our work lies in the creation of an annotated dataset for Bengali. By making this dataset publicly available[1], we hope to facilitate the comparison of different unsupervised POS induction algorithms and to stimulate interest in Bengali language processing.

The rest of the paper is organized as follows. Section 2 discusses related work on unsupervised POS induction. Section 3 describes our tagsets for English and Bengali. The next three sections describe the three steps of our bootstrapping approach: cluster the words using morphological information (Section 4), remove potentially mislabeled words from each cluster (Section 5), and bootstrap each cluster using a weakly supervised learner (Section 6). Finally, we present evaluation results in Section 7 and conclusions in Section 8.

2 Related Work

Several unsupervised POS induction algorithms have also attempted to incorporate morphological information into the distributional framework, but our work differs from these in two respects.

Computing morphological information. Previous POS induction algorithms have attempted to derive morphological information from dictionaries (Hajič, 2000) and knowledge-based morphological analyzers (Duh and Kirchhoff, 2006). However, these resources are generally not available for resource-scarce languages. Consequently, researchers have attempted to derive morphological information heuristically (e.g., Cucerzan and Yarowsky (2000), Clark (2003), Freitag (2004)). For instance, Cucerzan and Yarowsky (2000) posit a character sequence *x* as a suffix if there exists a sufficient number of distinct words *w* in the vocabulary such that the concatentations *wx* are also in the vocabulary. It is conceivable that such heuristically computed morphological information can be inaccurate, thus rendering the usefulness of a more accurate morphological analyzer. To address this problem, we exploit morphological information provided by an unsupervised word segmentation algorithm.

Tag	Description	Treebank tags
JJ	Adjective	JJ
JJR	Adjective, comparative	JJR
JJS	Adjective, superlative	JJS
NN	Singular noun	NN, NNP
NNS	Plural noun	NNS, NNPS
RB	Adverb	RB
VB	Verb, non-3rd ps. sing. present	VB, VBP
VBD	Verb, past tense or past participle	VBD, VBN
VBG	Verb, gerund/present participle	VBG
VBZ	Verb, 3rd ps. sing. present	VBZ

Table 1: The English tagset

Tag	Description	Examples
JJ	Adjective	vhalo, garam, kharap
NN	Singular noun	kanna, ridoy, shoshon
NN2	2nd order inflectional noun	dhopake, kalamtike
NN6	6th order inflectional noun	gharer, manusher
NN7	7th order inflectional noun	dhakai, barite, graame
NNP	Proper noun	arjun, ahmmad
NNS	Plural noun	manushgulo, pakhider
NNSH	Noun ending with "sh"	barish, jatrish
VB	Finite verb	kheyechi, krlam, krI
VBN	Non-finite verb	kre, giye, jete, kadte

Table 2: The Bengali tagset

Using morphological information. Perhaps due to the overly simplistic methods employed to compute morphological information, morphology has only been used as what Biemann (2006) called *add-on's* in existing POS induction algorithms, which remain primarily distributional in nature. In contrast, our approach more tightly integrates morphology into the distributional framework. As we will see, we train SVM classifiers using both morphological and distributional features to select seed words for our bootstrapping algorithm, effectively letting SVM combine these two sources of information and perform automatic feature weighting. Another appealing feature of our approach is that when labeling each unlabeled word with its POS tag, an SVM classifier also returns a numeric value that indicates how confident the word is labeled. This opens up the possibility of having a human improve our automatically constructed lexicon by manually checking those entries that are tagged with low confidence by an SVM classifier.

Recently, there have been attempts to perform (mostly) unsupervised POS tagging without relying on a POS lexicon. Haghighi and Klein's (2006) *prototype-driven* approach requires just a few prototype examples for each POS tag, exploiting these labeled words to constrain the labels of their distributionally similar words when training a generative log-linear model for POS tagging. Smith and Eisner (2005) train a log-linear model for POS tagging in an unsupervised manner using *contrastive estimation*, which seeks to move probability mass to a positive example *e* from its *neighbors* (i.e., negative examples created by perturbing *e*).

3 The English and Bengali Tagsets

Given our focus on automatically labeling open class words, our English and Bengali tagsets are designed to essentially cover all of the open-class words. Our English tagset, which is composed of ten tags, is shown in Table 1. As we can see, a tag in our tagset can be mapped to more than one Penn Treebank tags. For instance, we use the tag "NN" for both singular and plural common nouns. Our decision of which Penn Treebank tags to group together is based on that of Schütze (1995).

Our Bengali tagset, which also consists of ten tags, is adapted from the one proposed by Saha et al. (2004) (see Table 2). It is worth noting that unlike English, we assign different tags to Bengali proper nouns and common nouns. The reason is that for English, it is not particularly crucial to distinguish the two types of nouns during POS induction, since they can be distinguished fairly easily using heuristics such as initial capitalization. For Bengali, such simple heuristics do not exist, as the Bengali alphabet does not have any upper and lower case letters. Hence, it is important to distinguish Bengali proper nouns and common nouns during POS induction.

4 Clustering the Morphologically Similar Words

As mentioned before, our approach aims to more tightly integrate morphological information into the distributional POS induction framework. In fact, our POS induction algorithm begins by clustering the *morphologically similar* words (i.e., words that combine with the same set of suffixes). The motivation for clustering morphologically similar words can be attributed to our hypothesis that words having similar POS should combine with a similar set of suffixes. For instance, verbs in English combine with suffixes like "ing", "ed" and "s", whereas adjectives combine with suffixes like "er" and "est". Note, however, that the suffix "s" can attach to both verbs and nouns in English, and so it is not likely to be a useful feature for identifying the POS of a word. The question, then, is how to determine which suffixes are useful for the POS identification task in an *unsupervised* setting where we do not have any prior knowledge of language-specific grammatical constraints. This section proposes a method for identifying the "useful" suffixes and employing them to cluster the morphologically similar words. As we will see, our clustering algorithm not only produces soft clusters, but it also automatically determines the number of clusters for a particular language.

Before we describe how to identify the useful suffixes, we need to (1) induce all of the suffixes and (2) morphologically segment the words in our vocabulary.[2] However, neither of these tasks is simple for a truly resource-scarce language for which we do not have a dictionary or a knowledge-based morphological analyzer. As mentioned in the introduction, our proposed solution to both tasks is to use an unsupervised morphological analyzer that can be built just from an unannotated corpus. In particular, we have implemented an unsupervised morphological analyzer that outperforms Goldsmith's (2001) Linguistica and Creutz and Lagus's (2005) Morfessor for our English and Bengali datasets and compares favorably to the best-performing morphological parsers in MorphoChallenge 2005[3] (see Dasgupta and Ng (2007)).

Given the segmentation of each word and the most frequent 30 suffixes[4] provided by our morphological analyzer, our clustering algorithm operates by (1) clustering the similar suffixes and then (2) assigning words to each cluster based on the suffixes a word combines with. To cluster similar suffixes, we need to define the similarity between two suffixes. Informally, we say that two suffixes x and y are similar if a word that combines with x also combines with y and vice versa. In practice, we will rarely posit two suffixes as similar under this definition unless we assume access to a complete vocabulary – an assumption that is especially unrealistic for resource-scarce languages. As a result, we relax this definition and consider two suffixes x and y similar if $P(x \mid y) > t$ and $P(y \mid x) > t$, where $P(x \mid y)$ is the probability of a word combining with suffix x given that it combines with suffix y, and t is a threshold that we set to 0.4 in all of our experiments. Note that both probabilities can be estimated from an unannotated corpus.[5] Given this definition of similarity, we can cluster the similar suffixes using the following steps:

Creating the initial clusters. First, we create a *suffix graph*, in which we have (1) one node for each of the 30 suffixes, and (2) a directed edge from suffix x to suffix y if $P(y \mid x) > 0.4$. We then identify the strongly connected components of this graph using depth-first search. These strongly connected components define our initial partitioning of the 30 suffixes. We denote the suffixes assigned to a cluster the *primary keys* of the cluster.

Improving the initial clusters. Recall that we ultimately want to cluster the words by assigning each word w to the cluster in which w combines with all of its primary keys. Given this goal, it is conceivable that singleton clusters are not desirable. For instance, a cluster that has "s" as its only primary key is not useful, because although a lot of words combine with "s", they do not necessarily have the same POS. As a result, we improve each initial cluster by adding more suffixes to the cluster, in hopes of improving the resulting clustering of the words by placing additional constraints on each cluster. More specifically, we add a suffix y to a cluster c if, for each primary key x of c, $P(y \mid x) > 0.4$. If this condition is satisfied, then y becomes a *secondary key* of c. For each initial cluster c', we perform this check using each of the suffixes x' not in c' to see if x' can be added to c'. If, after this expansion step, we still have a cluster c* defined by a single primary key x that also serves as a secondary key in other clusters, then x is *probably ambiguous* (i.e., x can probably attach to words belonging to different POSs); and consequently, we remove c*. We denote the resulting set of clusters by C.

Populating the clusters with words. Next, for each word w in our vocabulary, we check whether w can be assigned to any of the clusters in C. Specifically, we assign w to a cluster c if w can combine with each of its primary keys and at least half of its secondary keys.

Labeling and merging the clusters. After populating each cluster with words, we manually label

[2] A vocabulary is simply a set of (distinct) words extracted from an unannotated corpus. We extracted our English and Bengali vocabulary from WSJ and Prothom Alo, respectively.

[3] http://www.cis.hut.fi/morphochallenge2005/

[4] We found that 30 suffixes are sufficient to cluster the words.

[5] For instance, we compute $P(x \mid y)$ as the ratio of the number of distinct words that combines with both x and y to the number of distinct words that combine with y only.

each of them with a POS tag from the tagset. We found that all of the clusters are labeled as NN, VB, or JJ. The reason is that the clustered words are mostly root words. We then merge all the clusters labeled with the same POS tag, yielding only three "big" clusters. Note that these "big" clusters are *soft* clusters, since a word can belong to more than one of them. For instance, "cool" can combine with "s" or "ing" to form a VB, and it can also combine with "er" or "est" to form a JJ.

Generating sub-clusters. Recall that each "big" cluster contains a set of suffixes and also a set of words that combines with those suffixes. Now, for each "big" cluster c, we create one sub-cluster c_x for each suffix x that appears in c. Then, for each word w in c, we use our unsupervised morphological analyzer to generate $w+x$ and add the surface form to the corresponding sub-cluster.

Labeling the sub-clusters. Finally, we manually label each sub-cluster with a POS tag from our tagset. For example, all the words ending in "ing" will be labeled as VBG. As before, we merge two clusters if they are labeled with the same POS tag. The resulting clusters are our morphologically formed clusters.

5 Purifying the Seed Set

The clusters formed thus far cannot be expected to be perfectly accurate, since (1) our unsupervised morphological analyzer is not perfect, and (2) morphology alone is not always sufficient for determining the POS of a word. In fact, we found that many adjectives are mislabeled as nouns for both languages. For instance, "historic" is labeled as a noun, since it combines with suffixes like "al" and "ally" that "accident" combines with. In addition, many words are labeled with the POS that does not correspond to their most common word sense. For instance, while words like "chair", "crowd" and "cycle" are more commonly used as nouns than verbs, they are labeled as verbs by our clustering algorithm. The reason is that suffixes that typically attach to verbs (e.g., "s", "ed", "ing") also attach to these words. Such labelings, though not incorrect, are undesirable, considering the fact that these words are to be used as seeds to bootstrap our morphologically formed clusters in a distributional manner. For instance, since "chair" and "crowd" are distributionally similar to nouns, their presence in the verb clusters can potentially contaminate the clusters with nouns during the bootstrapping process. Hence, for the purpose of effective bootstrapping, we also consider these words "mislabeled".

To identify the words that are potentially mislabeled, we rely on the following assumption: words that are morphologically similar should also be distributionally similar and vice versa. Based on this assumption, we propose a *purification* method that posits a word w as potentially mislabeled (and therefore should be removed or relabeled) if the POS of w as predicted using distributional information differs from that as determined by morphology.

The question, then, is how to predict the POS tag of a word using distributional information? Our idea is to use "supervised" learning, where we train and test on the seed set. Conceptually, we (1) train a *multi-class* classifier on the morphologically labeled words, each of which is represented by its context vector, and (2) apply the classifier to relabel the *same* set of words. If the new label of a word w differs from its original label, then morphology and context disagree upon the POS of w; and as mentioned above, our method then determines that the word is potentially misclassified. Note, however, that (1) the training instances are not perfectly labeled and (2) it does not make sense to train a classifier on data that is seriously mislabeled. Hence, we make the assumption that a large percentage (> 70%) of the training instances is correctly labeled[6], and that our method would work with a training set labeled at this level of accuracy. In addition, since we are training a classifier based on distributional features, we train and test on only *distributionally reliable* words, which we define to be words that appear at least five times in our corpus. Distributionally unreliable words will all be removed from the morphologically formed clusters, since we cannot predict their POS using distributional information.

In our implementation of this method, rather than train a multi-class classifier, we train a set of binary classifiers using SVM^{light} (Joachims, 1999) together with the distributional features for determining the POS tag of a given word.[7] More specifically, we train one classifier for each pair of

[6] An inspection of the morphologically formed clusters reveals that this assumption is satisfied for both languages.

[7] In this and all subsequent uses of SVM^{light}, we set all the training parameters to their default values.

POS tags. For instance, since we have ten POS tags for English, we will train 45 binary classifiers.[8] To determine the POS tag of a given English word w, we will use these 45 pairwise classifiers to independently assign a label to w. For instance, the NN-JJ classifier will assign either NN or JJ to w. We then count how many times w is tagged with each of the ten POS tags. If there is a POS tag t whose count is nine, it means that all the nine classifiers associated with t have classified w as t, and so our method will label w as t. Otherwise, we remove w from our seed set, since we cannot confidently label it using our classifier ensemble.

To create the training set for the NN-JJ classifier, for instance, we can possibly use all of the words labeled with NN and JJ as positive and negative instances, respectively. However, to ensure that we do not have a skewed class distribution, we use the same number of instances from each class to train the classifier. More formally, let I_{NN} be the set of instances labeled with NN, and I_{JJ} be the set of instances labeled with JJ. Without loss of generality, assume that $|I_{\mathrm{NN}}| < |I_{\mathrm{JJ}}|$, where $|X|$ denotes the size of the set X. To avoid class skewness, we have to sample from I_{JJ}, since it is the larger set. Our sampling method is motivated by bagging (Breiman, 1996). More specifically, we create 10 training sets from I_{JJ}, each of which has size $|I_{\mathrm{NN}}|$ and is formed by sampling with replacement from I_{JJ}. We then combine each of these 10 training sets separately with I_{NN}, and train 10 SVM classifiers from the 10 resulting training sets. Given a test instance i, we first apply the 10 classifiers independently to i and obtain the signed confidence values[9] of the predictions provided by the classifiers. We then take the average of the 10 confidence values, assigning i the positive class if the average is at least 0, and negative otherwise.

As mentioned above, we use distributional features to represent an instance created from a word w. The distributional features are created based on Schütze's (1995) method. Specifically, the left context and the right context of w are each encoded using the most frequent 500 words from the vocabulary. A feature in the left (right) context has the value 1 if the corresponding word appears to the left (right) of w in our corpus, and 0 otherwise. However, we found that using distributional features alone would erroneously classify words like "car" and "cars" as having the same POS because the two words are distributionally similar. In general, it is difficult to distinguish words in NN from those in NNS by distributional means. The same problem occurs for words in VB and VBD. To address this problem, we augment the feature set with suffixal features. Specifically, we create one binary feature for each of the 30 most frequent suffixes that we employed in the previous section. The feature corresponding to suffix x has the value 1 if x is the suffix of w. Moreover, we create an additional suffixal feature whose value is 1 if none of the 30 most frequent suffixes is the suffix of w.

6 Augmenting the Seed Set

After purification, we have a set of clusters filled with distributionally and morphologically reliable seed words that receive the same POS tag when predicted independently by morphological features and distributional features. Our goal in this section is to augment this seed set. Since we have a small seed set (5K words for English and 8K words for Bengali) and a large number of unlabeled words, we believe that it is most natural to apply a weakly supervised learning algorithm to bootstrap the clusters. Specifically, we employ a version of self-training together with SVM as the underlying learning algorithm.[10] Below we first present the high-level idea of our self-training algorithm and then discuss the implementation details.

Conceptually, our self-training algorithm works as follows. We first train a multi-class SVM classifier on the seed set for determining the POS tag of a word using the morphological and distributional features described in the previous section, and then apply it to label the unlabeled (i.e., unclustered) words. Words that are labeled with a confidence value that exceeds the current threshold (which is initially set to 1 and -1 for positively and negatively labeled instances, respectively) will be

[8] We could have trained just one 10-class classifier, but the fairly large number of classes leads us to speculate that this multi-class classifier will not achieve a high accuracy.

[9] Here, a large positive number indicates that the classifier confidently labels the instance as NN, and a large negative number represents confident prediction for JJ.

[10] As a related note, Clark's (2001) bootstrapping algorithm uses KL-divergence to measure the distributional similarity between an unlabeled word and a labeled word, adding to a cluster the words that are most similar to its current member. For us, SVM is a more appealing option because it automatically combines the morphological and distributional features.

added to the seed set. In the next iteration, we retrain the classifier on the augmented labeled data, apply it to the unlabeled data, and add to the labeled data those instances whose predicted confidence is above the current threshold. If none of the instances has a predicted confidence above the current threshold, we reduce the threshold by 0.1. (For instance, if the original thresholds are 1 and -1, they will be changed to 0.9 and -0.9.) We then repeat the above procedure until the thresholds reach 0.5 and -0.5. [11] Finally, we apply the resulting bootstrapped classifier to label all of the unlabeled words that have a corpus frequency of at least five, using a threshold of 0.

In our implementation of the self-training algorithm, rather than train a multi-class classifier in each bootstrapping iteration, we train pairwise classifiers (recall that for English, 45 classifiers are formed from 10 POS tags) using the morphological and distributional features described in the previous section. Again, since we employ distributional features, we apply the 45 pairwise classifiers only to the distributionally reliable words (i.e., words with corpus frequency at least 5). To classify an unlabeled word *w*, we apply the 45 pairwise classifiers to independently assign a label to *w*.[12] We then count how many times *w* is tagged with each of the ten POS tags. If there is a POS tag whose count is nine and all of these nine votes are associated with confidence that exceeds the current threshold, then we add *w* to the labeled data together with its assigned tag.

7 Evaluation

7.1 Experimental Setup

Corpora. Recall that our bootstrapping algorithm assumes as input an unannotated corpus from which we (1) extract our *vocabulary* (i.e., the set of words to be labeled) and (2) collect the statistics needed in morphological and distributional clustering. We use as our English corpus the Wall Street Journal (WSJ) portion of the Penn Treebank (Marcus et al., 1993). Our Bengali corpus is composed of five years of articles taken from the Bengali newspaper *Prothom Alo*.

Vocabulary creation. To extract our English vocabulary, we pre-processed each document in the WSJ corpus by first tokenizing them and then removing the most frequent 500 words (as they are mostly closed class words), capitalized words, punctuations, numbers, and unwanted character sequences (e.g., "***"). The resulting English vocabulary consists of approximately 35K words. We applied similar pre-processing steps to the Prothom Alo articles to generate our Bengali vocabulary, which consists of 80K words.

Test set preparation. Our English test set is composed of the 25K words in the vocabulary that appear at least five times in the WSJ corpus. The gold-standard POS tags for each word *w* are derived automatically from the parse trees in which *w* appears. To create the Bengali test set, we randomly chose 5K words from the vocabulary that appear at least five times in Prothom Alo. Each word in the test set was then labeled with its POS tags by two of our linguists.

Evaluation metric. Following Schütze (1995), we report performance in terms of recall, precision, and F1. Recall is the percentage of POS tags correctly proposed, precision is the percentage of POS tags proposed that are correct, and F1 is simply the harmonic mean of recall and precision. To exemplify, suppose the correct tagset for "crowd" is {NN, VB}; if our system outputs {VB, JJ, RB}, then recall is 50%, precision is 33%, and F1 is 40%. Importantly, all of our results will be reported on *word types*. This prevents the frequently occurring words from having a higher influence on the results than their infrequent counterparts.

7.2 Results and Discussion

The baseline system. We use as our baseline system one of the best existing unsupervised POS induction algorithms (Clark, 2003). More specifically, we downloaded from Clark's website[13] the code that implements a set of POS induction algorithms he proposed. Among these implementations, we chose *cluster_neyessenmorph*, which combines morphological and distributional infor-

[11] We decided to stop the bootstrapping procedure at thresholds of 0.5 and -0.5, because the more bootstrapping iterations we use, the lower are the quality of the bootstrapped data as well as the accuracy of the bootstrapped classifier.

[12] As in purification, each pairwise classifier is implemented as a set of 10 classifiers, each of which is trained on an equal number of instances from both classes. Testing also proceeds as before: the label of an instance is derived from the average of the confidence values returned by the 10 classifiers, and the confidence value associated with the label is just the average of the 10 confidence values.

[13] http://www.cs.rhul.ac.uk/home/alexc/

mation and achieves the best performance in his paper. When running his program, we use WSJ and Prothom Alo as the input corpora. In addition, we set the number of clusters produced to be 128, since this setting yields the best result in his paper. Results of the baseline system for the English and Bengali test sets are shown under the "After Bootstrapping" column in row 1 of Tables 3 and 4. As we can see, the baseline achieves F1-scores of 59% and 45% for English and Bengali, respectively. The other results in row 1 will be discussed below.

Our induction system. Recall that our unsupervised POS induction algorithm operates in three steps. To better understand the performance contribution of each of these steps, we show in row 2 of Tables 3 and 4 the results of our system after we (1) morphologically cluster the words, (2) purify the seed set, and (3) augment the seed set. Importantly, the numbers shown for each step are computed over the set of words in the test set that are labeled at the end of that step. For instance, the morphological clustering algorithm labeled 11K English words and 25K Bengali words, and so recall, precision and F1-score are computed over the subset of these labeled words that appear in the test set. Similarly, after bootstrapping, all the words that appear at least five times in our corpus are labeled; since our labeled data is now a superset of our test data, the numbers in the last column are the results of our algorithm for the entire test set.

As we can see, after morphological clustering, our system achieves F1-scores of 79% and 78% for English and Bengali, respectively. When measured on exactly the same set of words, the baseline only achieves F-scores of 59% and 56%. In fact, comparing rows 1 and 2, we outperform the baseline in each of the three steps of our algorithm. In particular, our system yields F1-scores of 73% and 77% for the entire English and Bengali test sets, thus outperforming the baseline by 14% and 18% for English and Bengali, respectively.

Two additional points deserve mentioning. First, for both languages, the highest F1-score is achieved after the purification step. A closer analysis of the labeled words reveals the reason. For English, many of the nouns incorrectly labeled as verbs by the morphological clustering algorithm were subsequently removed during the purification step when distributional similarity was used on top of morphological similarity. For Bengali, many proper nouns were assigned by the morphological clustering algorithm to the clusters dominated by common nouns (because the two types of Bengali nouns are morphologically similar), and many of these mislabeled proper nouns were subsequently removed during purification. Second, as expected, precision drops after the seed augmentation step, since the quality of the labeled data deteriorates as bootstrapping progresses. Nevertheless, with a lot more words labeled in the bootstrapping step, we still achieve F1-scores of 73% for English and 76% for Bengali.

The remaining rows of the Tables 3 and 4 show the performance of our algorithm for each tag in our two POS tagsets. Different observations can be made for the two languages. For English, the poor results for VBZ and NNS can be attributed to the fact that it is not easy to distinguish between these two tags: "s" is a typical suffix for words that are NNS and words that are the third person singular of a verb. In addition, results for verbs are better than those for nouns, since verbs are easier to identify using only morphological knowledge.

For Bengali, results for adjectives are not good, since (1) adjectives and nouns have very similar distributional property in Bengali and (2) there are not enough suffixes to induce the adjectives morphologically. Moreover, we achieve high precision but low recall for proper nouns. This implies that most of the words that our algorithm labels as proper nouns are indeed correct, but there are also many proper nouns that are mislabeled. A closer examination of the clusters reveals that many of these proper nouns are mislabeled as common nouns, presumably because these two types of Bengali nouns are morphologically and distributionally similar and therefore it is difficult to separate them. We will leave the identification of Bengali proper nouns as a topic for future research.

7.3 Additional Experiments

Labeling rare words with morphological information. Although our discussion thus far has focused on words whose corpus frequency is at least five, it would be informative to examine how well our algorithm performs on *rare, distributionally unreliable* words (i.e., words with corpus frequency less than five). Recall that our morphological clustering algorithm also clusters rare words. In fact, these rare words comprise 15% of the English words and 18% of the Bengali words in our morphological formed clusters. Perhaps more impor-

Table 4: POS induction results for Bengali based on word type

tantly, when measuring performance on just these morphologically clustered rare words, our algorithm achieves F1-scores of 81% and 79% for English and Bengali, respectively. These results provide empirical support for the claim that morphological information can be usefully employed to label rare words (Clark, 2003).

Soft clustering. Many words have more than one POS tag. For instance, "received" can be labeled as VBD and JJ. Although our morphological clustering algorithm can predict some of these ambiguities, those are at the "big" cluster level. At the sub-cluster level, the algorithm imposes a hard clustering on the words. In other words, no word appears in more than one sub-cluster.

Ideally, a POS induction algorithm should produce soft clusters due to lexical ambiguity. In fact, Jardino and Adda (1994), Schütze (1997) and Clark (2000) have attempted to address the ambiguity problem to a certain extent. We have also experimented with a very simple method for handling ambiguity in our bootstrapping algorithm: when augmenting the seed set, instead of labeling a word with a tag that receives 9 votes from the 45 pairwise classifiers, we label a word with any tag that receives at least 8 votes, effectively allowing the assignment of more than one label to a word. However, our experimental results (not shown due to space limitations) indicate that the incorporation of this method does not yield better overall performance, since many of the additional labels are erroneous and hence their presence deteriorates the quality of the bootstrapped data.

8 Conclusions

We have proposed a new bootstrapping algorithm for unsupervised POS induction. In contrast to existing algorithms developed for this problem, our algorithm is designed to (1) operate under a resource-scarce setting in which no language-specific tools or resources are available and (2) more tightly integrate morphological information with the distributional POS induction framework. In particular, our algorithm (1) improves the quality of the seed clusters by employing seed words that are distributionally and morphologically reliable and (2) uses support vector learning to combine morphological and distributional information. Our results show that it outperforms Clark's algorithm for English and Bengali, suggesting that it is applicable to both morphologically impoverished and highly inflectional languages.

Acknowledgements

We thank the five anonymous EMNLP-CoNLL referees for their valuable comments. We also thank Zeeshan Abedin and Mahbubur Rahman Haque for creating the Bengali lexicon.

Abstract

We introduce a relation extraction method to identify the sentences in biomedical text that indicate an interaction among the protein names mentioned. Our approach is based on the analysis of the paths between two protein names in the dependency parse trees of the sentences. Given two dependency trees, we define two separate similarity functions (kernels) based on cosine similarity and edit distance among the paths between the protein names. Using these similarity functions, we investigate the performances of two classes of learning algorithms, Support Vector Machines and k-nearest-neighbor, and the semi-supervised counterparts of these algorithms, transductive SVMs and harmonic functions, respectively. Significant improvement over the previous results in the literature is reported as well as a new benchmark dataset is introduced. Semi-supervised algorithms perform better than their supervised version by a wide margin especially when the amount of labeled data is limited.

1 Introduction

Protein-protein interactions play an important role in vital biological processes such as metabolic and signaling pathways, cell cycle control, and DNA replication and transcription (Phizicky and Fields, 1995). A number of (mostly manually curated) databases such as MINT (Zanzoni et al., 2002), BIND (Bader et al., 2003), and SwissProt (Bairoch and Apweiler, 2000) have been created to store protein interaction information in structured and standard formats. However, the amount of biomedical literature regarding protein interactions is increasing rapidly and it is difficult for interaction database curators to detect and curate protein interaction information manually. Thus, most of the protein interaction information remains hidden in the text of the papers in the biomedical literature. Therefore, the development of information extraction and text mining techniques for automatic extraction of protein interaction information from free texts has become an important research area.

In this paper, we introduce an information extraction approach to identify sentences in text that indicate an interaction relation between two proteins. Our method is different than most of the previous studies (see Section 2) on this problem in two aspects: First, we generate the dependency parses of the sentences that we analyze, making use of the dependency relationships among the words. This enables us to make more syntax-aware inferences about the roles of the proteins in a sentence compared to the classical pattern-matching information extraction methods. Second, we investigate semi-supervised machine learning methods on top of the dependency features we generate. Although there have been a number of learning-based studies in this domain, our methods are the first semi-supervised efforts to our knowledge. The high cost of labeling free text for this problem makes semi-supervised methods particularly valuable.

We focus on two semi-supervised learning methods: transductive SVMs (TSVM) (Joachims, 1999),

Proceedings of the 2007 Joint Conference on Empirical Methods in Natural Language Processing and Computational Natural Language Learning, pp. 228–237, Prague, June 2007. ©2007 Association for Computational Linguistics

and harmonic functions (Zhu et al., 2003). We also compare these two methods with their supervised counterparts, namely SVMs and k-nearest neighbor algorithm. Because of the nature of these algorithms, we propose two similarity functions (*kernels* in SVM terminology) among the instances of the learning problem. The instances in this problem are natural language sentences with protein names in them, and the similarity functions are defined on the positions of the protein names in the corresponding parse trees. Our motivating assumption is that the *path* between two protein names in a dependency tree is a good description of the semantic relation between them in the corresponding sentence. We consider two similarity functions; one based on the cosine similarity and the other based on the edit distance among such paths.

2 Related Work

There have been many approaches to extract protein interactions from free text. One of them is based on matching pre-specified patterns and rules (Blaschke et al., 1999; Ono et al., 2001). However, complex cases that are not covered by the pre-defined patterns and rules cannot be extracted by these methods. Huang *et al.* (2004) proposed a method where patterns are discovered automatically from a set of sentences by dynamic programming. Bunescu *et al.* (2005) have studied the performance of rule learning algorithms. They propose two methods for protein interaction extraction. One is based on the rule learning method Rapier and the other on longest common subsequences. They show that these methods outperform hand-written rules.

Another class of approaches is using more syntax-aware natural language processing (NLP) techniques. Both full and partial (shallow) parsing strategies have been applied in the literature. In partial parsing the sentence structure is decomposed partially and local dependencies between certain phrasal components are extracted. An example of the application of this method is relational parsing for the *inhibition* relation (Pustejovsky et al., 2002). In full parsing, however, the full sentence structure is taken into account. Temkin and Gilder (2003) used a full parser with a lexical analyzer and a context free grammar (CFG) to extract protein-protein interaction from text. Another study that uses full-sentence parsing to extract human protein interactions is (Daraselia et al., 2004). Alternatively, Yakushiji *et al.* (2005) propose a system based on head-driven phrase structure grammar (HPSG). In their system protein interaction expressions are presented as predicate argument structure patterns from the HPSG parser. These parsing approaches consider only syntactic properties of the sentences and do not take into account semantic properties. Thus, although they are complicated and require many resources, their performance is not satisfactory.

Machine learning techniques for extracting protein interaction information have gained interest in the recent years. The PreBIND system uses SVM to identify the existence of protein interactions in abstracts and uses this type of information to enhance manual expert reviewing for the BIND database (Donaldson et al., 2003). Words and word bigrams are used as binary features. This system is also tested with the Naive Bayes classifier, but SVM is reported to perform better. Mitsumori *et al.* (2006) also use SVM to extract protein-protein interactions. They use bag-of-words features, specifically the words around the protein names. These systems do not use any syntactic or semantic information. Sugiyama *et al.* (2003) extract features from the sentences based on the verbs and nouns in the sentences such as the verbal forms, and the part of speech tags of the 20 words surrounding the verb (10 before and 10 after it). Further features are used to indicate whether a noun is found, as well as the part of speech tags for the 20 words surrounding the noun, and whether the noun contains numerical characters, non-alpha characters, or uppercase letters. They construct k-nearest neighbor, decision tree, neural network, and SVM classifiers by using these features. They report that the SVM classifier performs the best. They use part-of-speech information, but do not consider any dependency or semantic information.

The paper is organized as follows. In Section 3 we describe our method of extracting features from the dependency parse trees of the sentences and defining the similarity between two sentences. In Section 4 we discuss our supervised and semi-supervised methods. In Section 5 we describe the data sets and evaluation metrics that we used, and present our results. We conclude in Section 6.

3 Sentence Similarity Based on Dependency Parsing

In order to apply the semi-supervised harmonic functions and its supervised counterpart kNN, and the kernel based TSVM and SVM methods, we need to define a similarity measure between two sentences. For this purpose, we use the dependency parse trees of the sentences. Unlike a syntactic parse (which describes the syntactic constituent structure of a sentence), the dependency parse of a sentence captures the semantic predicate-argument relationships among its words. The idea of using dependency parse trees for relation extraction in general was studied by Bunescu and Mooney (2005a). To extract the relationship between two entities, they design a kernel function that uses the shortest path in the dependency tree between them. The motivation is based on the observation that the shortest path between the entities usually captures the necessary information to identify their relationship. They show that their approach outperforms the dependency tree kernel of Culotta and Sorensen (2004), which is based on the subtree that contains the two entities. We adapt the idea of Bunescu and Mooney (2005a) to the task of identifying protein-protein interaction sentences. We define the similarity between two sentences based on the paths between two proteins in the dependency parse trees of the sentences.

In this study we assume that the protein names have already been annotated and focus instead on the task of extracting protein-protein interaction sentences for a given protein pair. We parse the sentences with the Stanford Parser[1] (de Marneffe et al., 2006). From the dependency parse trees of each sentence we extract the shortest path between a protein pair.

For example, Figure 1 shows the dependency tree we got for the sentence "*The results demonstrated that KaiC interacts rhythmically with KaiA, KaiB, and SasA.*" This example sentence illustrates that the dependency path between a protein pair captures the relevant information regarding the relationship between the proteins better compared to using the words in the unparsed sentence. Consider the protein pair KaiC and SasA. The words in the sentence between these proteins are *interacts*, *rhythmically*, *with*, *KaiA*, *KaiB*, and *and*. Among these words *rhythmically*, *KaiA*, *and* and *KaiB* are not directly related to the interaction relationship between KaiC and SasA. On the other hand, the words in the dependency path between this protein pair give sufficient information to identify their relationship.

In this sentence we have four proteins (KaiC, KaiA, KaiB, and SasA). So there are six pairs of proteins for which a sentence may or may not be describing an interaction. The following are the paths between the six protein pairs. In this example there is a single path between each protein pair. However, there may be more than one paths between a protein pair, if one or both appear multiple times in the sentence. In such cases, we select the shortest paths between the protein pairs.

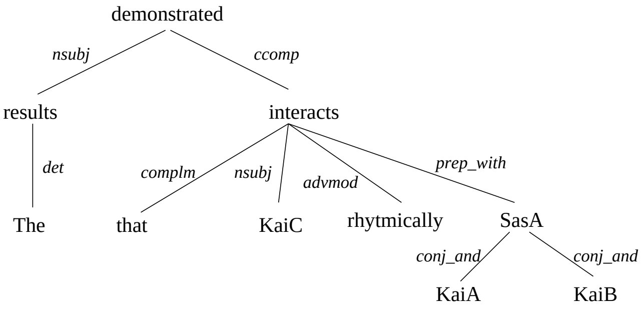

Figure 1: The dependency tree of the sentence "*The results demonstrated that KaiC interacts rhythmically with KaiA, KaiB, and SasA.*"

1. KaiC - nsubj - interacts - prep_with - SasA
2. KaiC - nsubj - interacts - prep_with - SasA - conj_and - KaiA
3. KaiC - nsubj - interacts - prep_with – SasA - conj_and - KaiB
4. SasA - conj_and - KaiA
5. SasA - conj_and - KaiB
6. KaiA – conj_and – SasA - conj_and - KaiB

If a sentence contains n different proteins, there are $\binom{n}{2}$ different pairs of proteins. We use machine learning approaches to classify each sentence as an interaction sentence or not for a protein pair. A sentence may be an interaction sentence for one protein

[1] http://nlp.stanford.edu/software/lex-parser.shtml

pair, while not for another protein pair. For instance, our example sentence is a positive interaction sentence for the *KaiC* and *SasA* protein pair. However, it is a negative interaction sentence for the *KaiA* and *SasA* protein pair, i.e., it does not describe an interaction between this pair of proteins. Thus, before parsing a sentence, we make multiple copies of it, one for each protein pair. To reduce data sparseness, we rename the proteins in the pair as *PROTX1* and *PROTX2*, and all the other proteins in the sentence as *PROTX0*. So, for our example sentence we have the following instances in the training set:

1. *PROTX1* - nsubj - interacts - prep_with - *PROTX2*
2. *PROTX1* - nsubj - interacts - prep_with - *PROTX0* - conj_and - *PROTX2*
3. *PROTX1* - nsubj - interacts - prep_with – *PROTX0* - conj_and - *PROTX2*
4. *PROTX1* - conj_and - *PROTX2*
5. *PROTX1* - conj_and - *PROTX2*
6. *PROTX1* – conj_and – *PROTX0* - conj_and - *PROTX2*

The first three instances are positive as they describe an interaction between *PROTX1* and *PROTX2*. The last three are negative, as they do not describe an interaction between *PROTX1* and *PROTX2*.

We define the similarity between two instances based on cosine similarity and edit distance based similarity between the paths in the instances.

3.1 Cosine Similarity

Suppose p_i and p_j are the paths between *PROTX1* and *PROTX2* in instance x_i and instance x_j, respectively. We represent p_i and p_j as vectors of term frequencies in the vector-space model. The cosine similarity measure is the cosine of the angle between these two vectors and is calculated as follows:

$$cos\_sim(p_i, p_j) = cos(\mathbf{p_i}, \mathbf{p_j}) = \frac{\mathbf{p_i} \bullet \mathbf{p_j}}{\|\mathbf{p_i}\|\|\mathbf{p_j}\|} \quad (1)$$

that is, it is the dot product of $\mathbf{p_i}$ and $\mathbf{p_j}$ divided by the lengths of $\mathbf{p_i}$ and $\mathbf{p_j}$. The cosine similarity measure takes values in the range $[0, 1]$. If all the terms in p_i and p_j are common, then it takes the maximum value of 1. If none of the terms are common, then it takes the minimum value of 0.

3.2 Similarity Based on Edit Distance

A shortcoming of cosine similarity is that it only takes into account the common terms, but does not consider their order in the path. For this reason, we also use a similarity measure based on edit distance (also called Levenshtein distance). Edit distance between two strings is the minimum number of operations that have to be performed to transform the first string to the second. In the original character-based edit distance there are three types of operations. These are insertion, deletion, or substitution of a single character. We modify the character-based edit distance into a word-based one, where the operations are defined as insertion, deletion, or substitution of a single word.

The edit distance between path 1 and path 2 of our example sentence is 2. We insert *PROTX0* and *conj_and* to path 1 to convert it to path 2.

1. *PROTX1* - nsubj - interacts - prep_with - **insert (*PROTX0*)** - **insert (*conj_and*)** – *PROTX2*
2. *PROTX1* - nsubj - interacts - prep_with - *PROTX0* - conj_and - *PROTX2*

We normalize edit distance by dividing it by the length (number of words) of the longer path, so that it takes values in the range $[0, 1]$. We convert the distance measure into a similarity measure as follows.

$$edit\_sim(p_i, p_j) = e^{-\gamma(edit\_distance(p_i, p_j))} \quad (2)$$

Bunescu and Mooney (2005a) propose a similar method for relation extraction in general. However, their similarity measure is based on the number of the overlapping words between two paths. When two paths have different lengths, they assume the similarity between them is zero. On the other hand, our edit distance based measure can also account for deletions and insertions of words.

4 Semi-Supervised Machine Learning Approaches

4.1 kNN and Harmonic Functions

When a similarity measure is defined among the instances of a learning problem, a simple and natural choice is to use a nearest neighbor based approach that classifies each instance by looking at the labels of the instances that are most similar to it. Perhaps the simplest and most popular similarity-based learning algorithm is the k-nearest neighbor classification method (kNN). Let U be the set of unlabeled instances, and L be the set of labeled instances in a learning problem. Given an instance $x \in U$, let $N_k^L(x)$ be the set of top k instances in L that are most similar to x with respect to some similarity measure. The kNN equation for a binary classification problem can be written as:

$$y(x) = \sum_{z \in N_k^L(x)} \frac{sim(x,z)y(z)}{\sum_{z' \in N_k^L(x)} sim(x,z')} \qquad (3)$$

where $y(z) \in \{0,1\}$ is the label of the instance z.[2] Note that $y(x)$ can take any real value in the $[0,1]$ interval. The final classification decision is made by setting a threshold in this interval (e.g. 0.5) and classifying the instances above the threshold as positive and others as negative. For our problem, each instance is a dependency path between the proteins in the pair and the similarity function can be one of the functions we have defined in Section 3.

Equation 3 can be seen as averaging the labels (0 or 1) of the nearest neighbors of each unlabeled instance. This suggests a generalized semi-supervised version of the same algorithm by incorporating unlabeled instances as neighbors as well:

$$y(x) = \sum_{z \in N_k^{L \cup U}(x)} \frac{sim(x,z)y(z)}{\sum_{z' \in N_k^{L \cup U}(x)} sim(x,z')} \qquad (4)$$

Unlike Equation 3, the unlabeled instances are also considered in Equation 4 when finding the nearest neighbors. We can visualize this as an undirected graph, where each data instance (labeled or unlabeled) is a node that is connected to its k nearest neighbor nodes. The value of $y(\cdot)$ is set to 0 or 1 for labeled nodes depending on their class. For each unlabeled node x, $y(x)$ is equal to the average of the $y(\cdot)$ values of its neighbors. Such a function that satisfies the average property on all unlabeled nodes is called a *harmonic* function and is known to exist and have a unique solution (Doyle and Snell, 1984). Harmonic functions were first introduced as a semi-supervised learning method by Zhu *et al.* (2003). There are interesting alternative interpretations of a harmonic function on a graph. One of them can be explained in terms of random walks on a graph. Consider a random walk on a graph where at each time point we move from the current node to one of its neighbors. The next node is chosen among the neighbors of the current node with probability proportional to the weight (similarity) of the edge that connects the two nodes. Assuming we start the random walk from the node x, $y(x)$ in Equation 4 is then equal to the probability that this random walk will hit a node labeled 1 before it hits a node labeled 0.

4.2 Transductive SVM

Support vector machines (SVM) is a supervised machine learning approach designed for solving two-class pattern recognition problems. The aim is to find the decision surface that separates the positive and negative labeled training examples of a class with maximum margin (Burges, 1998).

Transductive support vector machines (TSVM) are an extension of SVM, where unlabeled data is used in addition to labeled data. The aim now is to assign labels to the unlabeled data and find a decision surface that separates the positive and negative instances of the original labeled data and the (now labeled) unlabeled data with maximum margin. Intuitively, the unlabeled data pushes the decision boundary away from the dense regions. However, unlike SVM, the optimization problem now is NP-hard (Zhu, 2005). Pointers to studies for approximation algorithms can be found in (Zhu, 2005).

In Section 3 we defined the similarity between two instances based on the cosine similarity and the edit distance based similarity between the paths in the instances. Here, we use these path similarity measures as kernels for SVM and TSVM and modify the SVM^{light} package (Joachims, 1999) by plugging in our two kernel functions.

A well-defined kernel function should be symmetric positive definite. While cosine kernel is well-defined, Cortes *et al.* (2004) proved that edit kernel is not always positive definite. However, it is possible to make the kernel matrix positive definite by adjusting the γ parameter, which is a positive real number. Li and Jiang (2005) applied the edit kernel to predict initiation sites in eucaryotic mRNAs and

[2] Equation 3 is the weighted (or *soft*) version of the kNN algorithm. In the classical *voting* scheme, x is classified in the category that the majority of its neighbors belong to.

obtained improved results compared to polynomial kernel.

5 Experimental Results

5.1 Data Sets

One of the problems in the field of protein-protein interaction extraction is that different studies generally use different data sets and evaluation metrics. Thus, it is difficult to compare their results. Bunescu *et al.* (2005) manually developed the *AIMED* corpus[3] for protein-protein interaction and protein name recognition. They tagged 199 Medline abstracts, obtained from the Database of Interacting Proteins (DIP) (Xenarios et al., 2001) and known to contain protein interactions. This corpus is becoming a standard, as it has been used in the recent studies by (Bunescu et al., 2005; Bunescu and Mooney, 2005b; Bunescu and Mooney, 2006; Mitsumori et al., 2006; Yakushiji et al., 2005).

In our study we used the *AIMED* corpus and the *CB* (Christine Brun) corpus that is provided as a resource by BioCreAtIvE II (Critical Assessment for Information Extraction in Biology) challenge evaluation[4]. We pre-processed the CB corpus by first annotating the protein names in the corpus automatically and then, refining the annotation manually. As discussed in Section 3, we pre-processed both of the data sets as follows. We replicated each sentence for each different protein pair. For n different proteins in a sentence, $\binom{n}{2}$ new sentences are created, as there are that many different pairs of proteins. In each newly created sentence we marked the protein pair considered for interaction as *PROTX1* and *PROTX2*, and all the remaining proteins in the sentence as *PROTX0*. If a sentence describes an interaction between *PROTX1* and *PROTX2*, it is labeled as positive, otherwise it is labeled as negative. The summary of the data sets after pre-processing is displayed in Table 1[5].

Since previous studies that use AIMED corpus perform 10-fold cross-validation. We also performed 10-fold cross-validation in both data sets and report the average results over the runs.

Data Set	Sentences	+ Sentences	- Sentences
AIMED	4026	951	3075
CB	4056	2202	1854

Table 1: Data Sets

5.2 Evaluation Metrics

We use precision, recall, and F-score as our metrics to evaluate the performances of the methods. Precision (π) and recall (ρ) are defined as follows:

$$\pi = \frac{TP}{TP + FP}; \qquad \rho = \frac{TP}{TP + FN} \tag{5}$$

Here, TP (True Positives) is the number of sentences classified correctly as positive; FP (False Positives) is the number of negative sentences that are classified as positive incorrectly by the classifier; and FN (False Negatives) is the number of positive sentences that are classified as negative incorrectly by the classifier.
F-score is the harmonic mean of recall and precision.

$$F\text{-}score = \frac{2\pi\rho}{\pi + \rho} \tag{6}$$

5.3 Results and Discussion

We evaluate and compare the performances of the semi-supervised machine learning approaches (TSVM and harmonic functions) with their supervised counterparts (SVM and kNN) for the task of protein-protein interaction extraction. As discussed in Section 3, we use cosine similarity and edit distance based similarity as similarity functions in harmonic functions and kNN, and as kernel functions in TSVM and SVM. Our instances consist of the shortest paths between the protein pairs in the dependency parse trees of the sentences. In our experiments, we tuned the γ parameter of the edit distance based path similarity function to 4.5 with cross-validation. The results in Table 2 and Table 3 are obtained with 10-fold cross-validation. We report the average results over the runs.

Table 2 shows the results obtained for the AIMED data set. Edit distance based path similarity function performs considerably better than the cosine similarity function with harmonic functions and kNN and usually slightly better with SVM and TSVM. We achieve our best F-score performance of 59.96% with TSVM with edit kernel. While SVM with edit

[3] ftp://ftp.cs.utexas.edu/pub/mooney/bio-data/

[4] http://biocreative.sourceforge.net/biocreative_2.html

[5] The pre-processed data sets are available at http://belobog.si.umich.edu/clair/biocreative

kernel achieves the highest precision of 77.52%, it performs slightly worse than SVM with cosine kernel in terms of F-score measure. TSVM performs slightly better than SVM, both of which perform better than harmonic functions. kNN is the worst performing algorithm for this data set.

In Table 2, we also show the results obtained previously in the literature by using the same data set. Yakushiji *et al.* (2005) use an HPSG parser to produce predicate argument structures. They utilize these structures to automatically construct protein interaction extraction rules. Mitsumori *et al.* (2006) use SVM with the unparsed text around the protein names as features to extract protein interaction sentences. Here, we show their best result obtained by using the three words to the left and to the right of the proteins. The most closely related study to ours is that by Bunescu and Mooney (2005a). They define a kernel function based on the shortest path between two entities of a relationship in the dependency parse tree of a sentence (the SPK method). They apply this method to the domain of protein-protein interaction extraction in (Bunescu and Mooney, 2006). Here, they also test the methods ELCS (Extraction Using Longest Common Subsequences) (Bunescu et al., 2005) and SSK (Subsequence Kernel) (Bunescu and Mooney, 2005b). We cannot compare our results to theirs directly, because they report their results as a precision-recall graph. However, the best F-score in their graph seems to be around 0.50 and definitely lower than the best F-scores we have achieved (≈ 0.59). Bunescu and Mooney (2006) also use SVM as their learning method in their SPK approach. They define their similarity based on the number of overlapping words between two paths and assign a similarity of zero if the two paths have different lengths. Our improved performance with SVM and the shortest path dependency features may be due to the edit-distance based kernel, which takes into account not only the overlapping words, but also word order and accounts for deletions and insertions of words. Our results show that, SVM, TSVM, and harmonic functions achieve better F-score and recall performances than the previous studies by Yakushiji *et al.* (2005), Mitsumori *et al.* (2006), and the SSK and ELCS approaches of Bunescu and Mooney (2006). SVM and TSVM also achieve higher precision scores. Since, Mitsumori *et al.* (2006) also use SVM in their study, our improved results with SVM confirms our motivation of using dependency paths as features.

Table 3 shows the results we got with the CB data set. The F-score performance with the edit distance based similarity function is always better than that of cosine similarity function for this data set. The difference in performances is considerable for harmonic functions and kNN. Our best F-score is achieved with TSVM with edit kernel (85.22%). TSVM performs slightly better than SVM. When cosine similarity function is used, kNN performs better than harmonic functions. However, when edit distance based similarity is used, harmonic functions achieve better performance. SVM and TSVM perform better than harmonic functions. But, the gap in performance is low when edit distance based similarity is used with harmonic functions.

Method	Precision	Recall	F-Score

Table 3: Experimental Results – CB Data Set

Semi-supervised approaches are usually more effective when there is less labeled data than unlabeled data, which is usually the case in real applications. To see the effect of semi-supervised approaches we perform experiments by varying the amount of la-

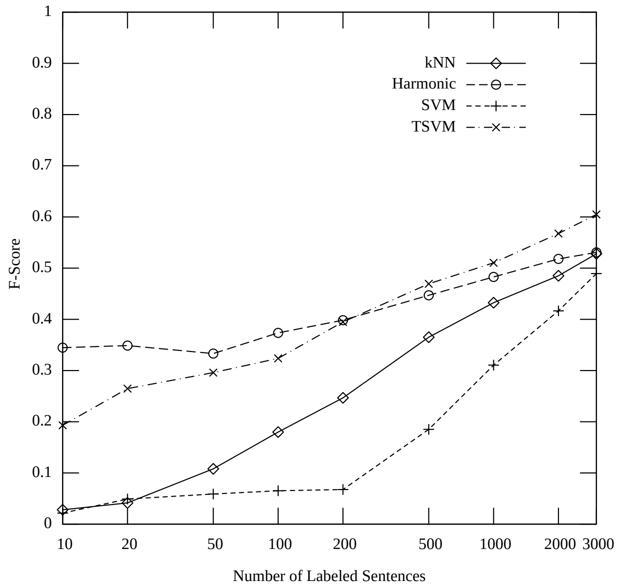

Figure 2: The F-score on the AIMED dataset with varying sizes of training data

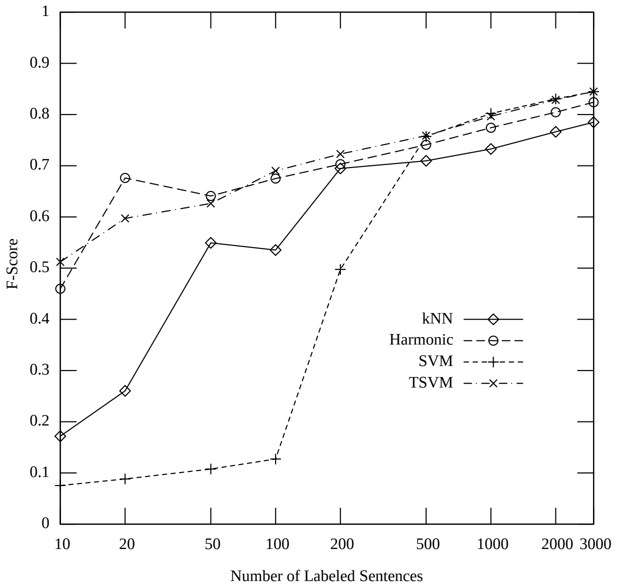

Figure 3: The F-score on the CB dataset with varying sizes of training data

beled training sentences in the range $[10, 3000]$. For each labeled training set size, sentences are selected randomly among all the sentences, and the remaining sentences are used as the unlabeled test set. The results that we report are the averages over 10 such random runs for each labeled training set size. We report the results for the algorithms when edit distance based similarity is used, as it mostly performs better than cosine similarity. Figure 2 shows the results obtained over the AIMED data set. Semi-supervised approaches TSVM and harmonic functions perform considerably better than their supervised counterparts SVM and kNN when we have small number of labeled training data. It is interesting to note that, although SVM is one of the best performing algorithms with more training data, it is the worst performing algorithm with small amount of labeled training sentences. Its performance starts to increase when number of training data is larger than 200. Eventually, its performance gets close to that of the other algorithms. Harmonic functions is the best performing algorithm when we have less than 200 labeled training data. TSVM achieves better performance when there are more than 500 labeled training sentences.

Figure 3 shows the results obtained over the CB data set. When we have less than 500 labeled sentences, harmonic functions and TSVM perform significantly better than kNN, while SVM is the worst performing algorithm. When we have more than 500 labeled training sentences, kNN is the worst performing algorithm, while the performance of SVM increases and gets similar to that of TSVM and slightly better than that of harmonic functions.

6 Conclusion

We introduced a relation extraction approach based on dependency parsing and machine learning to identify protein interaction sentences in biomedical text. Unlike syntactic parsing, dependency parsing captures the semantic predicate argument relationships between the entities in addition to the syntactic relationships. We extracted the shortest paths between protein pairs in the dependency parse trees of the sentences and defined similarity functions (kernels in SVM terminology) for these paths based on cosine similarity and edit distance. Supervised machine learning approaches have been applied to this domain. However, they rely only on labeled training data, which is difficult to gather. To our knowledge, this is the first effort in this domain to apply semi-supervised algorithms, which make use of both labeled and unlabeled data. We evaluated and compared the performances of two semi-supervised machine learning approaches (harmonic functions and TSVM), with their supervised counterparts (kNN and SVM). We showed that, edit distance based similarity function performs better than cosine similarity function since it takes into account not only common words, but also word order. Our 10-fold cross validation results showed that, TSVM performs slightly better than SVM, both of which perform better than harmonic functions. The worst performing algorithm is kNN. We compared our results with previous results published with the AIMED data set. We achieved the best F-score performance with TSVM with the edit distance kernel (59.96%) which is significantly higher than the previously reported results for the same data set.

In most real-world applications there are much more unlabeled data than labeled data. Semi-supervised approaches are usually more effective in these cases, because they make use of both the labeled and unlabeled instances when making decisions. To test this hypothesis for the application of extracting protein interaction sentences from text, we performed experiments by varying the number of labeled training sentences. Our results show that, semi-supervised algorithms perform considerably better than their supervised counterparts, when there are small number of labeled training sentences. An interesting result is that, in such cases SVM performs significantly worse than the other algorithms. Harmonic functions achieve the best performance when there are only a few labeled training sentences. As number of labeled training sentences increases the performance gap between supervised and semi-supervised algorithms decreases.

Abstract

We describe a discriminatively trained sequence alignment model based on the averaged perceptron. In common with other approaches to sequence modeling using perceptrons, and in contrast with comparable generative models, this model permits and transparently exploits arbitrary features of input strings. The simplicity of perceptron training lends more versatility than comparable approaches, allowing the model to be applied to a variety of problem types for which a learned edit model might be useful. We enumerate some of these problem types, describe a training procedure for each, and evaluate the model's performance on several problems. We show that the proposed model performs at least as well as an approach based on statistical machine translation on two problems of name transliteration, and provide evidence that the combination of the two approaches promises further improvement.

1 Introduction

Sequence alignment is a problem that crops up in many forms, both in computational linguistics (CL) and in other endeavors. The ability to find an optimal alignment between two sequences has found application in a number of areas of CL, including phonetic modeling (Ristad and Yianilos, 1998), name transcription (Huang et al., 2004), and duplicate detection or information integration (Bilenko and Mooney, 2003; McCallum et al., 2005). Sequence alignment is a member of a broader class of problems which we might call *sequence transduction*, to which one of the core CL challenges, machine translation, belongs.

Under the assumption that one string (the *target*) is produced through a series of local edits to another string (the *source*), and given an edit cost matrix, the optimal sequence of edits can be efficiently computed through dynamic programming (Needleman and Wunsch, 1970). While the cost matrix traditionally has been set by hand, several recent papers have proposed determining edit costs empirically. These proposals arise from a variety of learning paradigms, including generative models (Ristad and Yianilos, 1998; Bilenko and Mooney, 2003), conditional random fields (McCallum et al., 2005), maximum-margin methods (Joachims, 2003), and gradient boosting (Parker et al., 2006). While approaches based on generative models support only limited feature engineering, discriminative approaches share the advantage of allowing arbitrary features of the input sequences.

We describe a new sequence alignment model based on the averaged perceptron (Collins, 2002), which shares with the above approaches the ability to exploit arbitrary features of the input sequences, but is distinguished from them by its relative simplicity and the incremental character of its training procedure. The fact that it is an online algorithm makes it straightforward to adapt to a range of problems. To show this, we evaluate the approach on several different tasks, some of them merely illustrative, but some with clear practical significance,

Proceedings of the 2007 Joint Conference on Empirical Methods in Natural Language Processing and Computational Natural Language Learning, pp. 238–247, Prague, June 2007. ©2007 Association for Computational Linguistics

particularly the problem of named entity transcription.

2 The Algorithm

2.1 The Formalism

Suppose we are given two sequences, $\boldsymbol{s}_1^m \in \Sigma_s^*$ and $\boldsymbol{t}_1^n \in \Sigma_t^*$. We desire a real-valued function $A(\boldsymbol{s}, \boldsymbol{t})$ which assigns high scores to pairs $\boldsymbol{s}, \boldsymbol{t}$ with high *affinity*, where affinity is an application-specific notion (e.g., $\boldsymbol{t}$ is a likely phoneme sequence represented by the letter sequence $\boldsymbol{s}$). If we stipulate that this score is the sum of the individual scores of a series of edits, we can find the highest-scoring such series through a generalization of the standard edit distance:

$$A(\boldsymbol{s}_1^i, \boldsymbol{t}_1^j) = \max \begin{cases} a_{\epsilon,t_j}(\boldsymbol{s}, i, \boldsymbol{t}, j) + A(\boldsymbol{s}_1^i, \boldsymbol{t}_1^{j-1}) \\ a_{s_i,\epsilon}(\boldsymbol{s}, i, \boldsymbol{t}, j) + A(\boldsymbol{s}_1^{i-1}, \boldsymbol{t}_1^{j}) \\ a_{s_i,t_j}(\boldsymbol{s}, i, \boldsymbol{t}, j) + A(\boldsymbol{s}_1^{i-1}, \boldsymbol{t}_1^{j-1}) \end{cases} \quad (1)$$

with $A(\emptyset, \emptyset) = 0$. The function $a_{s_i,t_j}(\boldsymbol{s}, i, \boldsymbol{t}, j)$ represents the score of substituting t_j for s_i; a_{ϵ,t_j} and $a_{s_i,\epsilon}$ represent insertion and deletion, respectively. If we assume constant-time computation of primitive edit costs, this recursive definition of A allows us to find the highest scoring series of edits for a given sequence pair in time proportional to the product of their lengths. Note that a is indexed by the characters involved in an edit (i.e., inserting 'e' generally has a different cost than inserting 's'). Note further that the score associated with a particular operation may depend on any features computable from the respective positions in the two sequences.

In the experiments reported in this paper, we assume that each local function a is defined in terms of $p + q$ features, $\{f_1, \cdots, f_p, f_{p+1}, \cdots, f_{p+q}\}$, and that these features have the functional form $\Sigma^* \times \mathcal{N} \mapsto \mathcal{R}$. In other words, each feature takes a sequence and an index and returns a real value. The first p features are defined over sequences from the source alphabet, while the remaining q are defined over the target alphabet.[1] In this paper we use character n-gram indicator features.

```
Given a set $\boldsymbol{S}$ of source sequences
$V \leftarrow []$, an empty list
$\alpha \leftarrow \mathbf{0}$, a weight vector
for some number of iterations do
    for $\boldsymbol{s}$ in $\boldsymbol{S}$ do
        Pick $\boldsymbol{t}, \boldsymbol{t'}$, $\boldsymbol{t}$ having higher affinity with $\boldsymbol{s}$
        $\langle \boldsymbol{e}, v \rangle \leftarrow A_\alpha(\boldsymbol{s}, \boldsymbol{t})$
        $\langle \boldsymbol{e'}, v' \rangle \leftarrow A_\alpha(\boldsymbol{s}, \boldsymbol{t'})$
        if $v' \geq v$ then
            $\alpha \leftarrow \alpha + \Phi(\boldsymbol{s}, \boldsymbol{t}, \boldsymbol{e}) - \Phi(\boldsymbol{s}, \boldsymbol{t'}, \boldsymbol{e'})$
        end if
        Append $\alpha$ to $V$
    end for
end for
Return the mean $\alpha$ from $V$
```

Table 1: The training algorithm. A_α is the affinity function under model parameters α, returning edit sequence $\boldsymbol{e}$ and score v.

The score of a particular edit is a linear combination of the corresponding feature values:

$$a(\boldsymbol{s}, i, \boldsymbol{t}, j) = \sum_{k=1}^{p} \alpha_k \cdot f_k(\boldsymbol{s}, i) + \sum_{k=p+1}^{p+q} \alpha_k \cdot f_k(\boldsymbol{t}, j) \quad (2)$$

The weights α_k are what we seek to optimize in order to tune the model for our particular application.

2.2 A Perceptron-Based Edit Model

In this section we present a general-purpose extension of perceptron training for sequence labeling, due to Collins (2002), to the problem of sequence alignment. Take α to be a model parameterization, and let $A_\alpha(\boldsymbol{s}, \boldsymbol{t})$ return an optimal edit sequence $\boldsymbol{e}$, with its score v, given input sequences $\boldsymbol{s}$ and $\boldsymbol{t}$ under α. Elements of sequence $\boldsymbol{e}$ are character pairs $\langle c_s, c_t \rangle$, with $c_s \in \Sigma_s \cup \{\epsilon\}$ and $c_t \in \Sigma_t \cup \{\epsilon\}$, where ϵ represents the empty string. Let $\Phi(\boldsymbol{s}, \boldsymbol{t}, \boldsymbol{e})$ be a feature vector, having the same dimensionality as α, for a source, target, and corresponding edit sequence. This feature vector is the sum of feature vectors at each point in $\boldsymbol{e}$ as it is played out along input sequences $\boldsymbol{s}$ and $\boldsymbol{t}$.

Table 1 shows the basic algorithm. Starting with a zero parameter vector, we iterate through the collection of source sequences. For each sequence, we pick two target sequences having unequal affinity

[1] Of course, features that depend jointly on both sequences may also be of interest.

with the source sequence (Line 6). If the scores returned by our current model (Lines 7 and 8) agree with our ordering, we do nothing. Otherwise, we update the model using the perceptron training rule (Line 10). Ultimately, we return $\boldsymbol{\alpha}$ averaged over all datapoint presentations.

2.3 Training Modes

The algorithm presented in Table 1 does not specify how the two target sequences $\boldsymbol{t}$ and $\boldsymbol{t'}$ are to be chosen in Line 6. The answer to this question depends on the application. There are fundamentally two settings, depending on whether or not target strings are drawn from the same set as source strings; we will call the setting in which source and target strings inhabit the same set the *affinity* setting, and refer to the the case where they form different sets as the *transduction* setting. Here, we sketch four problem scenarios, two from each setting, and specify a target selection procedure appropriate for each.

Affinity, ranking. The task poses a latent affinity between strings, but we can measure it only indirectly. In particular, we can order *some* of the target sequences according to their affinity with a source sequence $\boldsymbol{s}$. In this case, we train as follows: Order a sample of the target sequences according to this partial order. Let $\boldsymbol{t}$ and $\boldsymbol{t'}$ be two sequences from this order, such that $\boldsymbol{t}$ is ordered higher than $\boldsymbol{t'}$.

Affinity, classification. The sequences in Σ^* can be grouped into classes, and we wish the model to assign high affinity to co-members of a class and low affinity to members of different classes. Train as follows: For each $\boldsymbol{s}$, sample $\boldsymbol{t}$ from among its co-members and $\boldsymbol{t'}$ from among the members of other classes.

Transduction, ranking. The data is presented as source-target pairs, where each $\boldsymbol{t}$ is a transduction of the corresponding $\boldsymbol{s}$. We wish to learn a model which, given a novel $\boldsymbol{s}$, will enable us to rank candidate transductions. Train as follows: Given $\boldsymbol{s}$, let $\boldsymbol{t}$ be the target sequence provided to us. Sample $\boldsymbol{t'}$ from among the other target sequences.

Transduction, generation. We are again given source-target pairs. We wish to learn to generate a probable target string, given a novel source string. Train as follows: *Generate* a $\boldsymbol{t'}$ that is approximately optimal according to the current model. Note that since edit decisions are based in part on (arbitrary) features of the target sequence, and since generation involves construction of the target sequence, it is not uncommon for a greedy generator to make edit decisions which are locally optimal, but which result several edits later in a partially constructed sequence in which no good edits are available. Thus, the problem of generation does not correspond to a simple recurrence relation like Equation 1. Consequently, we experimented with several heuristic approaches to generation and found that a beam search works well.

$\texttt{edit}_{\wedge}\texttt{ing}$	$\rightarrow$	$\texttt{STR}_{\wedge}\texttt{INGS}$
$f_{s,it\_}$		$f_{t,TR\_}$
$f_{s,t\_}$		$f_{t,R\_}$
$f_{s,\_in}$		$f_{\emptyset}$
$f_{s,\_i}$		

Table 2: Features with non-zero value for an example string pair and a model of order 2.

3 Evaluation

To establish the effectiveness of the model, we trained it on a range of problems, including instances of each of the four settings enumerated above. Problems ranged from the merely illustrative to a non-trivial application of computational linguistics.

3.1 Feature Construction

Without exception, the features we provide to the algorithm are the same in all experiments. Given a user-specified *order* k, we define a Boolean feature for every distinct character gram observed in the data of length k or smaller. Recall that there are two disjoint sets of features, those defined over strings drawn from the source and target alphabets, respectively. Given a source string and index, those features have value 1 whose corresponding grams (of size k or smaller) are observed preceding or following the index (preceding features are distinct from following ones); given a target string and index, we observe only preceding grams. Although it is possible to observe following grams in the target string in some settings, it is not possible in general (i.e., not when generating strings). We therefore adhere to this restriction for convenience and uniformity.

An example will make this clear. In Table 2 we are midway through the conversion of the source string “editing” into the target string “STRINGS”. Below the two strings are those gram features which have non-zero value at the indicated cursors. The underbar character encodes on which side of the cursor a gram is observed. Note that an empty-gram feature, which always tests true, is also included, allowing us to experiment with 0-order models.

3.2 Illustrative Problems

To test the ability of the model to recover known edit affinities, we experimented with a simple artificial problem. Using a large list of English words, we define an edit affinity that is sensitive only to consonants. Specifically, the affinity between two words is the maximum number of consonant self-substitutions, with any substitutions involving the first five consonants counting for five normal substitutions. Thus, substituting ‘b’ for ‘b’ contributes 5 to the score, substituting ‘z’ for ‘z’ contributes 1, while operations other than self-subsitutions, and any operations involving vowels, contribute 0.

One epoch of training is conducted as follows. For each word s in the training set, we choose 10 other words from the set at random and sort these words according to both the true and estimated affinity. Let t be the string with highest true affinity; let t' (the decoy) be the string with highest estimated affinity. We performed 3-fold cross-validation on a collection of 33,432 words, in each fold training the model for 5 epochs.[2]

Our performance metric is *ranking accuracy*, the fraction of target string pairs to which the estimated ranking assigns the same order as the true one. During testing, for each source string, we sample at random 1000 other strings from the hold-out data, and count the fraction of all pairs ordered correctly according to this criterion.

A 0-order model successfully learns to rank strings according to this affinity with 99.3% accuracy, while ranking according to the unmodified Levenshtein distance yields 76.4%. Table 3 shows the 6 averaged weights with the highest magnitude from a model trained on one of the folds. In presenting weights, we follow the formatting convention *edit*:*feature*. Since the model in question is of order 0, all features in Table 3 are the “empty feature.” Note how idempotent substitutions involving the 5 highly weighted consonants are weighted significantly higher than the remaining operations.

$\langle \texttt{d}, \texttt{d} \rangle$: $f_\emptyset$	61.1
$\langle \texttt{c}, \texttt{c} \rangle$: $f_\emptyset$	60.6
$\langle \texttt{g}, \texttt{g} \rangle$: $f_\emptyset$	60.3
$\langle \texttt{b}, \texttt{b} \rangle$: $f_\emptyset$	59.1
$\langle \texttt{f}, \texttt{f} \rangle$: $f_\emptyset$	57.0
$\langle \texttt{t}, \texttt{t} \rangle$: $f_\emptyset$	18.6

Table 3: Largest weights in a consonant-preserving edit affinity in which the first five consonants are given 5 times as much weight as others.

3.3 Rhyming

While the above problem illustrates the ability of the proposed algorithm to learn latent alignment affinities, it is expressible as a order-0 model. A somewhat more interesting problem is that of modeling groups of rhyming words. This problem is an instance of what we called the “classification” scenario in Section 2.3. Because English letters have long since lost their direct correspondence to phonemes, the problem of distinguishing rhyming English words is difficult for a knowledge-lean edit model. What’s more, the importance of a letter is dependent on context; letters near the end of a word are more likely to be significant.

We derived groups of rhyming words from the CMU pronouncing dictionary (CMU, 1995), discarding any singleton groups. This yielded 21,396 words partitioned into 3,799 groups, ranging in size from 464 words (nation, location, etc.) down to 2. We then divided the words in this data set at random into three groups for cross-validation.

Training was conducted as follows. For each word in the training set, we selected at random up to 5 rhyming words and 5 non-rhyming words. These words were ranked according to affinity with the source word under the current model. Let t be the lowest scoring rhyming word, and let t' be the highest-scoring non-rhyming word.

[2] Here and in other experiments involving the edit model, the number of epochs was set arbitrarily, and *not* based on performance on a development set. Beyond the number of epochs required for convergence, we have not observed much sensitivity in test accuracy to the number of epochs.

Model	*Precision*
Levenshtein	0.126
Longest common suffix	0.130
PTEM, Order 0	0.505
PTEM, Order 3	0.790

Table 4: Micro-averaged break-even precision on the task of grouping rhyming English words.

For each word in the hold-out set, we scored and ranked all rhyming words in the same set, as well as enough non-rhyming words to total 1000. We then recorded the precision at the point in this ranking where recall and precision are most nearly equal. Our summary statistic is the micro-averaged break-even precision.

Table 4 presents the performance of the proposed model and compares it with two simple baselines. Not surprisingly, performance increases with increasing order. The simple heuristic approaches fare quite poorly by comparison, reflecting the subtlety of the problem.

3.4 Transcription

Our work was motivated by the problem of named entity transcription. Out-of-vocabulary (OOV) terms are a persistent problem in statistical machine translation. Often, such terms are the names of entities, which typically have low corpus frequencies. In translation, the appropriate handling of names is often to transcribe them, to render them idiomatically in the target language in a way that preserves, as much as possible, their phonetic structure. Even when an OOV term is not a name, transcribing it preserves information that would otherwise be discarded, leaving open the possibility that downstream applications will be able to make use of it.

The state of the art in name transcription involves some form of generative model, sometimes in combination with additional heuristics. The generative component may involve explicitly modeling phonetics. For example, Knight and Graehl (1998) employ cascaded probabilistic finite-state transducers, one of the stages modeling the orthographic-to-phonetic mapping. Subsequently, Al-Onaizan and Knight (2002) find they can boost performance by combining a phonetically-informed model with one trained only on orthographic correspondences. Huang et al. (2004), construct a probabilistic Chinese-English edit model as part of a larger alignment solution, setting edit weights in a heuristic bootstrapped procedure.

Task	*Train*	*Dev*	*Eval*	*ELen*	*FLen*
A-E	8084	1000	1000	6.5	4.9
M-E	2000	430	1557	16.3	23.0

Table 5: Characteristics of the two transcription data sets, Arabic-English (A-E) and Mandarin-English (M-E), including number of training, development, and evaluation pairs (*Train*, *Dev*, and *Eval*), and mean length in characters of English and foreign strings (*ELen* and *FLen*).

In rendering unfamiliar written Arabic words or phrases in English, it is generally impossible to achieve perfect performance, because many sounds, such as short vowels, diphthong markers, and doubled consonants, are conventionally not written in Arabic. We calculate from our experimental datasets that approximately 25% of the characters in the English output must be inferred. Thus, a character error rate of 25% can be achieved through simple transliteration.

3.4.1 Transcribing names

We experimented with a list of 10,084 personal names distributed by the Linguistic Data Consortium (LDC). Each entry in the database includes an arabic name in transliterated ASCII (SATTS method) and its English rendering. The Arabic names appear as they would in conventional written Arabic, i.e., lacking short vowels and other diacritics. We randomly segregated 1000 entries for evaluation and used the rest for training. The *A-E* row in Table 5 summarizes some of this data set's characteristics.

We trained the edit model as follows. For each training pair the indicated English rendering constitutes our true target (t), and we use the current model to generate an alternate string (t'), updating the model in the event t' yields a higher score than t. This was repeated for 10 epochs. We experimented with a model of order 3.

Under this methodology, we observed a 1-best ac-

$\langle \texttt{p}, \texttt{h} \rangle$: $f_{t,a\_}$	38.5
$\langle \texttt{p}, \texttt{t} \rangle$: $f_{t,a\_}$	30.8
$\langle \texttt{p}, \texttt{h} \rangle$: $f_{t,ya\_}$	11.8

$\langle \texttt{p}, \texttt{h} \rangle$: $f_{t,rya\_}$	-12.1
$\langle \texttt{p}, \texttt{t} \rangle$: $f_{t,uba\_}$	-14.4

Table 6: Some of the weights governing the handling of the *tah marbouta* (ة) in an order-3 Arabic-English location name transcription model. Buckwalter encoding of Arabic characters is used here for purposes of display. The symbol “<e>” represents end of string.

curacy of 0.552. It is difficult to characterize the strength of this result relative to those reported in the literature. Al-Onaizan and Knight (2002) report a 1-best accuracy of 0.199 on a corpus of Arabic *person* names (but an accuracy of 0.634 on *English* names), using a “spelling-based” model, i.e., a model which has no access to phonetic information. However, the details of their experiment and model differ from ours in a number of respects.

It is interesting to see how a learned edit model handles ambiguous letters. Table 6 shows the weights of some of the features governing the handling of the character ة (*tah marbouta*) from experiments with Arabic place names. This character, which represents the “t” sound, typically appears at the end of words. It is generally silent, but is spoken in certain grammatical constructions. In its silent form, it is typically transcribed “ah” (or “a”); in its spoken form, it is transcribed “at”. The weights in the table reflect this ambiguity and illustrate some of the criteria by which the model chooses the appropriate transcription. For example, the negative weight on the feature $f_{s,\_p<e>}$ inhibits the production of “t” at the end of a phrase, where “h” is almost always more appropriate. Similarly, “h” is more common following “ya” in the target string (often as part of the larger suffix “iyah”). However, the preceding context “rya” is usually observed in the word “qaryat”, meaning “village” as in “the village of ...” In this grammatical usage, the tah marbouta is spoken and therefore rendered with a “t”. Consequently, the corresponding weight in the “h” interpretation is inhibitory.

The Al-Onaizan and Knight spelling model can be regarded as a statistical machine translation (SMT) system which translates source language characters to target language characters in the absence of phonetic information. For comparison with state of the art, we used the RWTH phrase-based SMT system (Zens et al., 2005) to build an Arabic-to-English transliteration system. This system frames the transcription problem as follows. We are given a sequence of source language characters s_1^m representing a name, which is to be translated into a sequence of target language characters t_1^n. Among all possible target language character sequences, we will choose the character sequence with the highest probability:

$$\hat{t}_1^{\hat{n}} = \underset{n,t_1^n}{\operatorname{argmax}} \{\Pr(t_1^n|s_1^m)\} \qquad (3)$$

The posterior probability $\Pr(t_1^n|s_1^m)$ is modeled directly using a log-linear combination of several models (Och and Ney, 2002), including a character-based phrase translation model, a character-based lexicon model, a 4-gram character sequence model, a character penalty and a phrase penalty. The first two models are used for both directions: Arabic to English and English to Arabic. We do not use any reordering model because the target character sequence is always monotone with respect to the source character sequence. More details about the baseline system can be found in (Zens et al., 2005).

We remark in passing that while the perceptron-based edit model is a general algorithm for learning sequence alignments using simple features, the above SMT approach combines several models, some of which have been the subject of research in the fields of speech recognition and machine translation for several years. Furthermore, we made an effort to optimize the performance of the SMT approach on the tasks presented here.

Table 7 compares this system with the edit model. The difference between the 1-best accuracies of the two systems is significant at the 95% level, using the bootstrap for testing. However, we can improve on both systems by combining them. We segregated 1000 training documents to form a development set, and used it to learn linear combination coefficients over our two systems, resulting in a combined system that scored 0.588 on the evaluation set—a sta-

Model	*1best*	*5best*
SMT	0.528	0.824
PTEM, Order 3	0.552	0.803
Linear combination	0.588	0.850

tistically significant improvement over both systems at the 95% confidence level.

3.4.2 Ranking transcriptions

In some applications, instead of transcribing a name in one language into another, it is enough just to rank candidate transcriptions. For example, we may be in possession of comparable corpora in two languages and the means to identify named entities in each. If we can rank the likely transcriptions of a name, we may be able to align a large portion of the transliterated named entities, potentially extending the coverage of our machine translation system, which will typically have been developed using a smaller parallel corpus. This idea is at the heart of several recent attempts to improve the handling of named entities in machine translation (Huang et al., 2004; Lee and Chang, 2003). A core component of all such approaches is a generative model similar in structure to the "spelling" model proposed by Al-Onaizan and Knight.

When ranking is the objective, we can adopt a training procedure that is much less expensive than the one used for generation. Let t be the correct transcription for a source string (s). Sample some number of strings at random (200 in the following experiments) from among the transcriptions in the training set of strings other than s. Let t' be the string having highest affinity with s, updating the model, as usual, if t' scores higher than t.

In addition to the Arabic-English corpus, we also experiment with a corpus distributed by the LDC of full English names paired with their Mandarin spelling. The *M-E* row of Table 5 summarizes characteristics of this data set. Because we are interested in an approximate comparison with similar experiments in the literature, we selected at random 2430 for training and 1557 for evaluation, which are the data sizes used by Lee and Chang (2003) for their experiments. In these experiments, the Chinese names are represented as space-separated pinyin without tonal markers.

Note that this problem is probably harder than the Arabic one, for several reasons. For one thing, the letters in a Mandarin transcription of a foreign name represent syllables, leading to a somewhat lossier rendering of foreign names in Mandarin than in Arabic. On a more practical level, this data set is noisier, occasionally containing character sequences in one string for which corresponding characters are lacking from its paired string. On the other hand, the Mandarin problem contains full names, rather than name components, which provides more context for ranking.

We trained the edit model on both data sets using both the sampling procedure outlined above and the self-generation training regime, in each case for 20 epochs, producing models of orders from 1 to 3. However, we found that the efficiency of the phrase-based SMT system described in the previous section would be limited for this task, mainly due to two reasons: the character-based phrase models due to possible unseen phrases in an evaluation corpus, and the character sequence model as all candidate transcriptions confidently belong to the target language. Therefore, to make the phrase-based SMT system robust against data sparseness for the ranking task, we also make use of the IBM Model 4 (Brown et al., 1993) in both directions. The experiments show that IBM Model 4 is a reliable model for the ranking task. For each evaluation pair, we then ranked all available evaluation transcriptions, recording where in this list the true transcription fell.

Table 8 compares the various models, showing the fraction of cases for which the true transcription was ranked highest, and its mean reciprocal rank (MRR). Both the phrase-based SMT model and the edit model perform well on this task. While the best configuration of PTEM out-performs the best SMT model, the differences are not significant at the 95% confidence level. However, compare these performance scores to those returned by the system of Lee and Chang (2003), who reported a peak MRR of 0.82 in similar experiments involving data different from ours.

The PTEM rows in the table are separated into

Model	C-E Task		A-E Task	
	ACC	MRR	ACC	MRR
SMT	0.795	0.797	0.982	0.985
SMT w/o LM	0.797	0.798	0.983	0.985
IBM_4	0.961	0.971	0.978	0.987
SMT + IBM_4	0.971	0.977	0.991	0.994
PTEM*G*, Ord. 1	0.843	0.877	0.959	0.975
PTEM*G*, Ord. 2	0.970	0.978	0.968	0.980
PTEM*G*, Ord. 3	0.975	0.982	0.971	0.983
PTEM*R*, Ord. 1	0.961	0.973	0.992	0.995
PTEM*R*, Ord. 2	0.960	0.972	0.989	0.993
PTEM*R*, Ord. 3	0.960	0.972	0.989	0.994

Table 8: Performance on two transcription ranking tasks, showing fraction of cases in which the correct transcription was ranked highest, accuracy (ACC) and mean reciprocal rank of the correct transcription (MRR).

those in which the model was trained using the same procedure as for generation (PTEM*G*), and those in which the quicker ranking-specific training regime was used (PTEM*R*). The comparison is interesting, inasmuch it does not support the conclusion that one regime is uniformly superior to the other. While generation regime yields the best performance on Arabic (using a high-order model), the ranking regime scores best on Mandarin (with a low-order model). When training a model to generate, it seems clear that more context in the form of larger n-grams is beneficial. This is particularly true for Mandarin, where an order-1 model probably does not have the capacity to generate plausible decoys.

4 Discussion

This paper is not the first to show that perceptron training can be used in the solution of problems involving transduction. Both Liang, et al (2006), and Tillmann and Zhang (2006) report on effective machine translation (MT) models involving large numbers of features with discriminatively trained weights. The training of these models is an instance of the “Generation” scenario outlined in Section 2.3. However, because machine translation is a more challenging problem than name transcription (larger vocabularies, higher levels of ambiguity, non-monotonic transduction, etc.), our general-purpose approach to generation training may be intractable for MT. Instead, much of the focus of these papers are the heuristics that are required in order to train such a model in this fashion, including feature selection using external resources (phrase tables), staged training, and generating to BLEU-maximal sequences, rather than the reference target.

Klementiev and Roth (2006) explore the use of a perceptron-based ranking model for the purpose of finding name transliterations across comparable corpora. They do not calculate an explicit alignment between strings. Instead, they decompose a string pair into a collection of features derived from character n-grams heuristically paired based on their locations in the respective strings. Thus, Klementiev and Roth, in common with the two MT approaches described above, carefully control the features used by the perceptron. In contrast to these approaches, our algorithm discovers *latent* alignments, essentially selecting those features necessary for good performance on the task at hand.

As noted in the introduction, several previous papers have proposed general, discriminatively trained sequence alignment models, as alternatives to the generative model proposed by Ristad and Yianilos. McCallum, et al. (2005), propose a conditional random field for sequence alignment, designed for the important problem of duplicate detection and information integration. Comprising two sub-models, one for matching strings and one for non-matching, the model is trained on sequence pairs explicitly labeled “match” or “non-match,” and some care is apparently needed in selecting appropriate non-matching strings. It is therefore unclear how this model would be extended to problems involving ranking or generation.

Joachims (2003) proposes SVM-align, a sequence alignment model similar in structure to that described here, but which sets weights through direct numerical optimization. Training involves exposing the model to sequence pairs, along with the correct alignment and some number of “decoy” sequences. The reliance on an explicit alignment and hand-chosen decoys yields a somewhat less flexible solution than that presented here. It is not clear whether these features of the training regime are indispensable, or whether they might be generalized to increase the approach's scope. Note that where directly maximizing the margin is feasible, it has been shown empirically to be superior to perceptron training (Altun et al., 2003).

Parker et al. (2006), propose to align sequences by gradient tree boosting. This approach has the attractive characteristic that it supports a factored representation of edits (a characteristic it shares with McCallum et al.). Although this paper does not evaluate the method on any problems from computational linguistics (the central problem is musical information retrieval), gradient tree boosting has been shown to be an effective technique for other sorts of sequence modeling drawn from computational linguistics (Dietterich et al., 2004).

5 Conclusion

Motivated by the problem of Arabic-English transcription of names, we adapted recent work in perceptron learning for sequence labeling to the problem of sequence alignment. The resulting algorithm shows clear promise not only for transcription, but also for ranking of transcriptions and structural classification. We believe this versatility will lead to other successful applications of the idea, both within computational linguistics and in other fields involving sequential learning.

Instance Based Lexical Entailment for Ontology Population

Claudio Giuliano and **Alfio Gliozzo**

Abstract

In this paper we propose an instance based method for lexical entailment and apply it to automatic ontology population from text. The approach is fully unsupervised and based on kernel methods. We demonstrate the effectiveness of our technique largely surpassing both the random and most frequent baselines and outperforming current state-of-the-art unsupervised approaches on a benchmark ontology available in the literature.

1 Introduction

Textual entailment is formally defined as a relationship between a coherent text T and a language expression, the hypothesis H. T is said to entail H, denoted by $T \rightarrow H$, if the meaning of H can be inferred from the meaning of T (Dagan et al., 2005; Dagan and Glickman., 2004). Even though this notion has been recently proposed in the computational linguistics literature, it has already attracted a great attention due to the very high generality of its settings and to the indubitable usefulness of its (potential) applications.

In this paper, we concentrate on the problem of lexical entailment, a textual entailment subtask in which the system is asked to decide whether the substitution of a particular word w with the word e in a coherent text $H_w = H^l w H^r$ generates a sentence $H_e = H^l e H^r$ such that $H_w \rightarrow H_e$, where H^l and H^r denote the left and the right context of w, respectively. For example, given the word ‘weapon’ a system may substitute it with the synonym ‘arm’, in order to identify relevant texts that denote the sought concept using the latter term. A particular case of lexical entailment is recognizing synonymy, where both $H_w \rightarrow H_e$ and $H_e \rightarrow H_w$ hold.

In the literature, slight variations of this problem are also referred to as *sense matching* (Dagan et al., 2006), *lexical reference* (Glickman et al., 2006a) and *lexical substitution* (Glickman et al., 2006b). They have been applied to a wide variety of tasks, such as semantic matching, subtitle generation and Word Sense Disambiguation (WSD). Modeling lexical entailment is also a prerequisite to approach the SemEval-2007 lexical substitution task[1], consisting of finding alternative words that can occur in given context.

In this paper, we propose to apply an approach for lexical entailment to the ontology population task. The basic idea is that if a word entails another one in a given context then the former is an instance or a subclass of the latter. This approach is intuitively appealing because lexical entailment is intrinsically an unsupervised task, therefore it does not require lexical resources, seed examples or manually annotated data sets. Unsupervised approaches are particularly suited for ontology population, whose goal is to find instances of concepts from corpora, because both corpus and the ontology sizes can scale up to millions of documents and thousands of concepts, preventing us from applying supervised learning. In addition, the top level part of the ontology (i.e., the *Tbox* in the Description Logics terminology) is very

[1] http://nlp.cs.swarthmore.edu/semeval/tasks/task10/description.shtml

Proceedings of the 2007 Joint Conference on Empirical Methods in Natural Language Processing and Computational Natural Language Learning, pp. 248–256, Prague, June 2007. ©2007 Association for Computational Linguistics

often modified during the ontology engineering lifecycle, for example by introducing new concepts and restructuring the subclass_of hierarchy according to the renewed application needs required by the evolution of the application domain. It is evident that to preserve the consistency between the Tbox and the *Abox* (i.e., the set of instances and their relations) in such a dynamic ontology engineering process, supervised approaches are clearly inadequate, as small changes in the TBox will be reflected into dramatic annotation effort to keep instances in the Abox aligned.

The problem of populating a predefined ontology of concepts with novel instances implies a WSD task, as the entities in texts are ambiguous with respect to the domain ontology. For example, the entity *Washington* is both the name of a state and the name of a city. In the ontology population settings traditional WSD approaches cannot be directly applied since entities are not reported into dictionaries, making the lexical entailment alternative more viable. In particular, we model the problem of ontology population as the problem of recognizing for each mention of an entity of a particular coarse-grained type (e.g., location) the fine-grained concept (e.g., lake or mountain) that can be substituted in texts preserving the meaning. For example, in the sentence "the first man to climb the Everest without oxygen", "Everest" can be substituted with the word *mountain* preserving the meaning, while the sentence is meaningless when "Everest" is replaced with the word *lake*. Following the lexical entailment approach, the ontology population task is transformed into the problem of recognizing the term from a fine-grained set of categories (e.g., city, country, river, lake and mountain) that can be substituted in the contexts where the entity is mentioned (e.g., Everest in the example above).

The main contributions of this paper are summarized as follows. First, we propose a novel approach to lexical entailment, called Instance Based Lexical Entailment (IBLE), that allows approaching the problem as a classification task, in which a given target word (i.e., the entailing word) in a particular context is judged to entail a different word taken from a (pre-defined) set of (possible) candidate entailed words (see Section 3). Second, we exploit the IBLE approach to model the ontology population task as follows. Given a set of candidate concepts belonging to generic ontological types (e.g., people or locations), and a set of pre-recognized mentions of entities of these types in the corpus (e.g., Newton, Ontario), we assign the entity to the class whose lexicalization is more frequently entailed in the corpus. In particular, as training set to learn the fine-grained category models, we use all the occurrences of their corresponding expressions in the same corpus (e.g., we collected all occurrences in context of the word *scientist* to describe the concept `scientist`). Then, we apply the trained model to classify the pre-recognized coarse-grained entities into the fine-grained categories.

Our approach is fully unsupervised as for training it only requires occurrences of the candidate entailed words taken in their contexts. Restricted to the ontology population task, for each coarse-grained entity (e.g., location), the candidate entailed words are the terms corresponding to the fine-grained classes (e.g., lake or mountain) and the entailing words are mentions of entities (e.g., New York, Ontario) belonging to the coarse-grained class, recognized by an entity tagger.

Experiments show that our method for recognizing lexical entailment is effective for the ontology population task, reporting improvements over a state-of-the-art unsupervised technique based on contextual similarity measures (Cimiano and Völker, 2005). In addition, we also compared it to a supervised approach (Tanev and Magnini, 2006), that we regarded as an upper bound, obtaining comparable results.

2 The Ontology Population Task

Populating concepts of a predefined ontology with instances found in a corpus is a primary goal of knowledge management systems. As concepts in the ontology are generally structured into hierarchies belonging to a common ontological type (e.g., people or locations), the problem of populating ontologies can be solved hierarchically, firstly identifying instances in texts as belonging to the topmost concepts, and then assigning them to a fine-grained class. Supervised named entity recognition (NER) systems can be used for accomplishing the first step. State-of-the-art NER systems are characterized by high accuracy, but they require a large amount of training data. However, domain specific ontologies generally contains many "fine-grained" categories (e.g., particular categories of people, such as writers, scientists, and so on) and, as a consequence, supervised methods cannot be used because the annotation costs would become prohibitive.

Therefore, in the literature, the fine-grained classification task has been approached by adopting weakly supervised (Tanev and Magnini, 2006; Fleischman and Hovy, 2002) or unsupervised methods (Cimiano and Völker, 2005). Tanev and Magnini (2006) proposed a weakly supervised method that requires as training data a list of terms without context for each class under consideration. Such list can be automatically acquired from existing ontologies or other sources (i.e., database fields, web sites like Wikipedia, etc.) since the approach imposes virtually no restrictions on them. Given a generic syntactically parsed corpus containing at least each training entity twice, the algorithm learns, for each class, a feature vector describing the contexts where those entities occur. Then it compares the new (unknown) entity with the so obtained feature vectors, assigning it to the most similar class. Fleischman and Hovy (2002) approached the ontology population problem as a classification task, providing examples of instances in their context as training examples for their respective fine-grained categories.

The aforementioned approaches are clearly inadequate to recognize such fine-grained distinctions, as they would require a time consuming and costly annotation process for each particular class, that is clearly infeasible when the number of concepts in the ontology scales up. Therefore, most of the present research in ontology population is focusing on either unsupervised approaches (Cimiano and Völker, 2005) or weakly supervised approaches (Tanev and Magnini, 2006).

Unsupervised approaches are mostly based on term similarity metrics. Cimiano and Völker (2005) assign a particular entity to the fine-grained class such that the contextual similarity is maximal among the set of fine-grained subclasses of a coarse-grained category. Contextual similarity has been measured by adopting lexico-syntactic features provided by a dependency parser, as proposed in (Lin, 1998).

3 Instance Based Lexical Entailment

Dagan et al. (2006) adapted the classical supervised WSD setting to approach the sense matching problem (i.e., the binary lexical entailment problem of deciding whether a word, such as *position*, entails a different word, such as *job*, in a given context) by defining a one-class learning algorithm based on support vector machines (SVM). They train a one-class model for each entailed word (e.g., all the occurrences of the word *job* in the corpus) and, then, apply it to classify all the occurrences of the entailing words (e.g., the word *position*), providing a binary decision criterion[2]. Similarly to the WSD case, examples are represented by feature vectors describing their contexts, and then compared to the feature vectors describing the context of the target word.

In this paper, we adopt a similar strategy to approach a multi-class lexical entailment problem. The basic hypothesis is that if a word w entails e in a particular context ($H_w \rightarrow H_e$), then some of the contexts T_e^j in which e occurs in the training corpus are similar to H_w. Given a word w and an (exhaustive) set of candidate entailed words $E = \{e_1, e_2, \ldots, e_n\}$, to which we refer hereafter with the expression "substitution lexica", our goal is to select the word $e_i \in E$ that can be substituted to w in the context H_w generating a sentence H_e such that $H_w \rightarrow H_e$. In the multi-class setting, supervised learning approaches can be used. In particular, we can apply a one-versus-all learning methodology, in which each class e_i is trained from both positive (i.e., all the occurrences of e_i in the corpus) and negative examples (i.e., all the occurrences of the words in the set $\{e_j | j \neq i\}$).

Our approach is clearly a simplification of the more general lexical entailment settings, where given two generic words w and e, and a context $H = H^l w H^r$, the system is asked to decide whether w entails e or not. In fact, the latter is a binary classification problem, while the former is easier as the system is required to select "the best" option among the substitution lexicon. Of course providing such set could be problematic in many cases (e.g., it could be incomplete or simply not available for

[2] This approach resembles the pseudo-words technique proposed to evaluate WSD algorithms at the earlier stages of the WSD studies (Gale et al., 1992), when large scale sense tagged corpora were not available for training supervised algorithms.

many languages or rare words). On the other hand, such a simplification is practically effective. First of all, it allows us to provide both positive and negative examples, avoiding the use of one-class classification algorithms that in practice perform poorly (Dagan et al., 2006). Second, the large availability of manually constructed substitution lexica, such as WordNet (Fellbaum, 1998), or the use of repositories based on statistical word similarities, such as the database constructed by Lin (1998), allows us to find an adequate substitution lexicon for each target word in most of the cases.

For example, as shown in Table 1, the word *job* has different senses depending on its context, some of them entailing its direct hyponym *position* (e.g., "looking for permanent *job*"), others entailing the word *task* (e.g., "the *job* of repairing"). The problem of deciding whether a particular instance of *job* can be replaced by *position*, and not by the word *place*, can be solved by looking for the most similar contexts where either *position* or *place* occur in the training data, and then selecting the class (i.e., the entailed word) characterized by the most similar ones, in an instance based style. In the first example (see row 1), the word *job* is strongly associated to the word *position*, because the contexts of the latter in the examples 1 and 2 are similar to the context of the former, and not to the word *task*, whose contexts (4, 5 and 6) are radically different. On the other hand, the second example (see row 2) of the word *job* is similar to the occurrences 4 and 5 of the word *task*, allowing its correct substitution.

It is worthwhile to remark that, due to the ambiguity of the entailed words (e.g., *position* could also entail either *perspective* or *place*), not every occurrence of them should be taken into account, in order to avoid misleading predictions caused by the irrelevant senses. Therefore, approaches based on a more classical contextual similarity technique (Lin, 1998; Dagan, 2000), where words are described "globally" by context vectors, are doomed to fail. We will provide empirical evidence of this in the evaluation section.

Choosing an appropriate similarity function for the contexts of the words to be substituted is a primary issue. In this work, we exploited similarity functions already defined in the WSD literature, relying on the analogy between the lexical entailment and the WSD task. The state-of-the-art supervised WSD methodology, reporting the best results in most of the Senseval-3 lexical sample tasks in different languages, is based on a combination of syntagmatic and domain kernels (Gliozzo et al., 2005) in a SVM classification framework. Therefore, we adopted exactly the same strategy for our purposes.

A great advantage of this methodology is that it is totally corpus based, as it does not require neither the availability of lexical databases, nor the use of complex preprocessing steps such as parsing or anaphora resolution, allowing us to apply it on different languages and domains once large corpora are available for training. Therefore, we exploited exactly the same strategy to implement the IBLE classifier required for our purposes, defining a kernel composed by n simple kernels, each representing a different aspect to be considered when estimating contextual similarity among word occurrences. In fact, by using the closure properties of the kernel functions, it is possible to define the kernel combination schema as follows[3]:

$$K_C(x_i, x_j) = \sum_{l=1}^{n} \frac{K_l(x_i, x_j)}{\sqrt{K_l(x_j, x_j) K_l(x_i, x_i)}}, \quad (1)$$

where K_l are valid kernel functions, measuring similarity between the objects x_i and x_j from different perspectives[4].

One means to satisfy both the WSD and the lexical entailment requirements is to consider two different aspects of similarity: domain aspects, mainly related to the topic (i.e., the global context) of the texts in which the word occurs, and syntagmatic aspects, concerning the lexico-syntactic pattern in the local context. Domain aspects are captured by the domain kernel, described in Section 3.1, while syntagmatic aspects are taken into account by the syntagmatic kernel, presented in Section 3.2.

[3] Some recent works (Zhao and Grishman, 2005; Gliozzo et al., 2005) empirically demostrate the effectiveness of combining kernels in this way, showing that the combined kernel always improves the performance of the individual ones. In addition, this formulation allows evaluating the individual contribution of each information source.

[4] An exhaustive discussion about kernel methods for NLP can be found in (Shawe-Taylor and Cristianini, 2004).

Entailed	*job*		*Training*
position	... looking for permanent academic **job** in ...	1	... from entry-level through permanent **positions**.
		2	My academic **position** ...
		3	... put the lamp in the left **position** ...
task	The **job** of repairing	4	The **task** of setting up ...
		5	Repairing the engine is an hard **task**.
		6	... **task** based evaluation.

Table 1: IBLE example.

3.1 The Domain Kernel

(Magnini et al., 2002) claim that knowing the domain of the text in which the word is located is a crucial information for WSD. For example the (domain) polysemy among the `Computer_Science` and the `Medicine` senses of the word `virus` can be solved by simply considering the domain of the context in which it is located. Domain aspects are also crucial in recognizing lexical entailment. For example, the term `virus` entails `software_agent` in the `Computer_Science` domain (e.g., "The laptop has been infected by a *virus*"), while it entails *bacterium* when located in the `Medicine` domain (e.g., "HIV is a *virus*"). As argued in (Magnini et al., 2002), domain aspects can be considered by analyzing the lexicon in a large context of the word to be disambiguated, regardless of the actual word order. We refer to (Gliozzo et al., 2005) for a detailed description of the domain kernel. The simplest methodology to estimate the domain similarity among two texts is to represent them by means of vectors in the Vector Space Model (VSM), and to exploit the cosine similarity. The VSM is a k-dimensional space $\mathbb{R}^k$, in which the text t_j is represented by means of the vector $\vec{t_j}$ such that the i^{th} component of $\vec{t_j}$ is the term frequency of the term w_i in it. The similarity between two texts in the VSM is estimated by computing the cosine between them, providing the kernel function K_{VSM} that can be used as a basic tool to estimate domain similarity between texts[5].

3.2 The Syntagmatic Kernel

Syntagmatic aspects are probably the most important evidence for recognizing lexical entailment. In general, the strategy adopted to model syntagmatic relations in WSD is to provide bigrams and trigrams of collocated words as features to describe local contexts (Yarowsky, 1994). The main drawback of this approach is that non contiguous or shifted collocations cannot be identified, decreasing the generalization power of the learning algorithm. For example, suppose that the word *job* has to be disambiguated into the sentence "…permanent academic *job* in…", and that the occurrence "We offer permanent *positions*…" is provided for training. A traditional feature mapping would extract the context words w_{-1}:`academic`, w_{-2}:`permanent` to represent the former, and w_{-1}:`permanent`, w_{-2}:`offer` to index the latter. Evidently such features will not match, leading the algorithm to a misclassification.

The syntagmatic kernel, proposed by Gliozzo et al. (2005), is an attempt to solve this problem. It is based on a gap-weighted subsequences kernel (Shawe-Taylor and Cristianini, 2004). In the spirit of kernel methods, this kernel is able to compare sequences directly in the input space, avoiding any explicit feature mapping. To perform this operation, it counts how many times a (non-contiguous) subsequence of symbols u of length n occurs in the input string s, and penalizes non-contiguous occurrences according to the number of the contained gaps. To define our syntagmatic kernel, we adapted the generic definition of the sequence kernels to the problem of recognizing collocations in local word contexts. We refer to (Giuliano et al., 2006) for a detailed description of the syntagmatic kernel.

[5] In (Gliozzo et al., 2005), in addition to the standard VSM, a domain kernel, exploiting external information acquired from unlabeled data, has been also used to reduce the amount of (labeled) training data. Here, given that our approach is fully unsupervised, i.e., we can obtain as many examples as we need, we do not use the domain kernel.

4 Lexical Entailment for Ontology Population

In this section, we apply the IBLE technique, described in Section 3, to recognize lexical entailment for ontology population. To this aim, we cast ontology population as a lexical entailment task, where the fine-grained categories are the candidate entailed words, and the named entities to be subcategorized are the entailing words. Below, we present the main steps of our algorithm in details.

Step 1 By using a state-of-the-art supervised NER system, we recognize the named entities belonging to a set of coarse-grained categories (e.g., location and people) of interest for the domain.

Step 2 For all fine-grained categories belonging to the same coarse-grained type, we extract from a domain corpus all the occurrences of their lexicalizations in context (e.g., for the category `actor`, we extract all contexts where the term *actor* occurs), and use them as input to train the IBLE classifier. In this way, we obtain a multi-class classifier for each ontological type. Then, we classify all the occurrences of the named entities recognized in the first step. The output of this process is a list of tagged named entities; where the elements of the list could have been classified into different fine-grained categories even though they refer to the same phrase (e.g., the occurrences of the entity "Jack London" could have been classified both as `writer` and `actor`, depending on the contexts where they occur).

Step 3 A distinct category is finally assigned to the entities referring to the same phrase in the list. This is done on the basis of the tags that have been assigned to all its occurrences during the previous step. To this purpose, we implemented a voting mechanism. The basic idea is that an entity belongs to a specific category if its occurrences entail a particular superclass "more often than expected by chance", where the expectation is modeled on the basis of the overall distribution of fine-grained category labels, assigned during the second step, in the corpus. This intuition is formalized by applying a statistical reliability measure, that depends on the distribution of positive assignments for each class, defined by the following formula:

$$R(e, c) = \frac{P(c|e) - \mu_c}{\sigma_c}, \tag{2}$$

where $P(c|e)$ is estimated by the relative frequency of the fine-grained class c among the different occurrences of the entity e, μ_c and σ_c measure the mean and the standard deviation of the distribution $P(c|E)$, and E is an (unlabeled) training set of instances of the coarse-grained type classified by the IBLE algorithm. Finally, each entity is assigned to the category c^* such that

$$c^* = \underset{c}{argmax}\; R(e, c). \tag{3}$$

5 Evaluation

Evaluating a lexical entailment algorithm in itself is rather complex. Therefore, we performed a task driven evaluation of our system, measuring its usefulness in an ontology population task, for which evaluation benchmarks are available, allowing us to compare our technique to existing state-of-the-art approaches.

As introduced in Section 4, the ontology population task can be modeled as a lexical entailment problem, in which the fine-grained classes are the entailed words and the named entities belonging to the coarse-grained ontological type are the entailing words.

In the following, we first introduce the experimental settings (Section 5.1). Then we evaluate our technique by comparing it to state-of-the-art unsupervised approaches for ontology population (Section 5.2).

5.1 Experimental Settings

For all experiments, we adopted the evaluation benchmark proposed in (Tanev and Magnini, 2006). It considers two high-level named entity categories both having five fine-grained sub-classes (i.e., `mountain`, `lake`, `river`, `city`, and `country` as subtypes of LOCATION; `statesman`, `writer`, `athlete`, `actor`, and `inventor` are subtypes of PERSON). The authors used WordNet and Wikipedia as primary data sources for populating the evaluation ontology. In total, the ontology is populated with 280 instances which were not ambiguous (with respect to the ontology) and appeared at least twice in the English CLEF corpus[6]. Even the evaluation task is rather small and can be perceived as an artificial experimental setting, it is the best available benchmark we can use to compare our system to existing approaches in the literature, as we are not aware of other available resources.

To perform NER we used CRFs (Lafferty et al., 2001). We trained a first-order CRF on the MUC data set to annotate locations and people. In our experiments, we used the implementation provided in MALLET (McCallum, 2002). We used a standard feature set inspired by the literature on text chunking and NER (Tjong Kim Sang and Buchholz, 2000; Tjong Kim Sang and De Meulder, 2003; Tjong Kim Sang, 2002) to train a first-order CRFs. Each instance is represented by encoding all the following families of features, all time-shifted by -2,-1,0,1,2: (a) the word itself, (b) the PoS tag of the token, (c) orthographic predicates, such as *capitalization*, *upper-case*, *numeric*, *single character*, and *punctuation*, (d) gazetteers of locations, people names and organizations, (e) character-n-gram predicates for 2 $\leqslant n \leqslant$ 3.

As an (unsupervised) training set for the fine-grained categories, we exploited all occurrences in context of their corresponding terms we found in the CLEF corpus (e.g., for the category `actor` we used all the occurrences of the term *actor*). We did not use any prior estimation of the class frequency, adopting a pure unsupervised approach. Table 2 lists the fine-grained concepts and the number of the training examples found for each of them in the CLEF corpus.

As a reference for a comparison of the outcomes of this study, we used the results presented in (Tanev and Magnini, 2006) for the Class-Word and Class-Example approaches. The Class-Word approach exploits a similarity metric between terms and concepts based on the comparison of the contexts where they appear. Details of this technique can be found in (Cimiano and Völker, 2005). Tanev and Magnini (2006) proposed a variant of the Class-Word algorithm, called Class-Example, that relies on syntactic features extracted from corpus and uses as an additional input a set of training examples for each class. Overall, it required $1,194$ examples to accomplish this task.

All experiments were performed using the SVM package *LIBSVM*[7] customized to embed our own kernel. In all the experiments, we used the default parameter setting.

location		**person**	
mountain	1681	statesman	119
lake	730	writer	3436
river	1411	athlete	642
city	35000	actor	2356
country	15037	inventor	105

Table 2: Number of training examples for each class.

5.2 Results

Table 4 shows our results compared with two baselines (i.e., random and most frequent, estimated from the test data) and the two alternative approaches for ontology population described in the previous section. Our system outperforms both baselines and largely surpasses the Class-Word unsupervised method.

It is worthwhile to remark here that, being the IBLE algorithm fully unsupervised, improving the most frequent baseline is an excellent result, rarely achieved in the literature on unsupervised methods for WSD (McCarthy et al., 2004). In addition, our system is also competitive when compared to supervised approaches, being it only 5 points lower than the Class-Example method, while it does not require seed examples and syntactic parsing. This characteristic makes our system flexible and adaptable to different languages and domains.

System	**Micro F1**	**Macro F1**
RND Baseline	0.20	0.20
Class-Word	0.42	0.33
MF baseline	0.52	NA
IBLE	0.57	0.47
Class-Example	0.62	0.68

Table 3: Comparison of different ontology population techniques.

[6] `http://www.clef-campaign.org`

[7] `http://www.csie.ntu.edu.tw/~cjlin/libsvm/`

Finally, we performed a disaggregated evaluation of our system, assessing the performance for different ontological types and different concepts. Results show that our method performs better on larger fine-grained classes (i.e., `writer` and `country`), while the results on smaller categories are affected by low recall, even if the predictions provided by the system tends to be highly accurate. Taking into consideration that our system is fully unsupervised, this behavior is highly desirable because it implies that it is somehow able to identify the predominant class. In addition the high precision on the smaller classes can be explained by our instance based approach.

Person	**N**	**Prec**	**Rec**	**F1**
Inventor	11	1	0.18	0.31
Statesman	20	1.0	0.05	0.10
Writer	88	0.61	0.89	0.72
Actor	25	0.57	0.68	0.62
Athlete	20	1	0.1	0.18

6 Conclusions and Future Work

In this paper, we presented a novel unsupervised technique for recognizing lexical entailment in texts, namely instance based lexical entailment, and we exploited it to approach an ontology population task. The basic assumption is that if a word is entailed by another in a given context, then some of the contexts of the entailed word should be similar to that of the word to be disambiguated. Our technique is effective, as it largely surpasses both the random and most frequent baselines. In addition, it improves over the state-of-the-art for unsupervised approaches, achieving performances close to the supervised rivaling techniques requiring hundreds of examples for each class.

Ontology population is only one of the possible applications of lexical entailment. For the future, we plan to apply our instance based approach to a wide variety of tasks, e.g., lexical substitution, word sense disambiguation and information retrieval. In addition, we plan to exploit our lexical entailment as a subcomponent of a more complex system to recognize textual entailment. Finally, we are going to explore more elaborated kernel functions to recognize lexical entailment and more efficient learning strategies to apply our method to web-size corpora.

Acknowledgments

The authors would like to thank Bernardo Magnini and Hristo Tanev for providing the benchmark, Ido Dagan for useful discussions and comments regarding the connections between lexical entailment and ontology population, and Alberto Lavelli for his thorough review. Abstract

To date, work on Non-Local Dependencies (NLDs) has focused almost exclusively on English and it is an open research question how well these approaches migrate to other languages. This paper surveys non-local dependency constructions in Chinese as represented in the Penn Chinese Treebank (CTB) and provides an approach for generating proper predicate-argument-modifier structures including NLDs from surface context-free phrase structure trees. Our approach recovers non-local dependencies at the level of Lexical-Functional Grammar f-structures, using automatically acquired subcategorisation frames and f-structure paths linking antecedents and traces in NLDs. Currently our algorithm achieves 92.2% f-score for trace insertion and 84.3% for antecedent recovery evaluating on gold-standard CTB trees, and 64.7% and 54.7%, respectively, on CTB-trained state-of-the-art parser output trees.

1 Introduction

A substantial number of linguistic phenomena such as topicalisation, relativisation, coordination and raising & control constructions, permit a constituent in one position to bear the grammatical role associated with another position. These relationships are referred to Non-Local Dependencies (NLDs), where the surface location of the constituent is called “antecedent”, and the site where the antecedent should be interpreted semantically is called “trace”. Capturing non-local dependencies is crucial to the accurate and complete determination of semantic interpretation in the form of predicate-argument-modifier structures or deep dependencies.

However, with few exceptions (Model 3 of Collins, 1999; Schmid, 2006), output trees produced by state-of-the-art broad coverage statistical parsers (Charniak, 2000; Bikel, 2004) are only surface context-free phrase structure trees (CFG-trees) without empty categories and coindexation to represent displaced constituents. Because of the importance of non-local dependencies in the proper determination of predicate-argument structures, recent years have witnessed a considerable amount of research on reconstructing such hidden relationships in CFG-trees. Three strategies have been proposed: (i) post-processing parser output with pattern matchers (Johnson, 2002), linguistic principles (Campbell, 2004) or machine learning methods (Higgins, 2003; Levy and Manning, 2004; Gabbard et al., 2006) to recover empty nodes and identify their antecedents;[1] (ii) integrating non-local dependency recovery into the parser by enriching a simple PCFG model with GPSG-style gap features (Collins, 1999; Schmid, 2006); (iii) pre-processing the input sentence with a finite-state trace tagger which detects empty nodes before parsing, and identify the antecedents on the parser output with the gap information (Dienes and Dubey, 2003a; Dienes and Dubey, 2003b).

In addition to CFG-oriented approaches, a number of richer treebank-based grammar acquisition and parsing methods based on HPSG (Miyao et al., 2003), CCG (Clark and Hockenmaier, 2002), LFG (Riezler et al., 2002; Cahill et al., 2004) and Dependency Grammar (Nivre and Nilsson, 2005) incorporate non-local dependencies into their deep syntactic or semantic representations.

A common characteristic of all these approaches

[1] (Jijkoun, 2003; Jijkoun and Rijke, 2004) also describe post-processing methods to recover NLDs, which are applied to syntactic dependency structures converted from CFG-trees.

Proceedings of the 2007 Joint Conference on Empirical Methods in Natural Language Processing and Computational Natural Language Learning, pp. 257–266, Prague, June 2007.

is that, to date, the research has focused almost entirely on English,[2] despite the disparity in type and frequency of non-local dependencies for various languages. In this paper, we address recovering non-local dependencies for Chinese, a language drastically different from English and whose special features such as lack of morphological inflection make NLD recovery more challenging. Inspired by (Cahill et al., 2004)'s methodology which was originally designed for English and Penn-II treebank, our approach to Chinese non-local dependency recovery is based on Lexical-Functional Grammar (LFG), a formalism that involves both phrase structure trees and predicate-argument structures. NLDs are recovered in LFG f-structures using automatically acquired subcategorisation frames and finite approximations of functional uncertainty equations describing NLD paths at the level of f-structures.

The paper is structured as follows: in Section 2 we outline the distinguishing features of Chinese non-local dependencies compared to English. In Section 3 we review (Cahill et al., 2004)'s method for recovering English NLDs in treebank-based LFG approximations. In Section 4, we describe how we modify and substantially extend the previous method to recover all types of NLDs for Chinese data. We present experiments and provide a dependency-based evaluation in Section 5. Finally we conclude and summarise future work.

2 Non-Local Dependencies in Chinese

In the Penn Chinese Treebank (CTB) (Xue et al., 2002) non-local dependencies are represented in terms of empty categories (ECs) and (for some of them) coindexation with antecedents, as exemplified in Figure 1. Following previous work for English and the CTB annotation scheme, we use “non-local dependencies” as a cover term for all missing or dislocated elements represented in the CTB as an empty category (with or without coindexation/antecedent), and our use of the term remains agnostic about fine-grained distinctions between non-local dependencies drawn in the theoretical linguistics literature.

In order to give an overview on the characteristics of Chinese non-local dependencies, we extracted all empty categories together with coindexed antecedents from the Penn Chinese Treebank version 5.1 (CTB5.1). Table 1 gives a breakdown of the most frequent types of empty categories and their antecedents, which account for 43,791 of the total 43,954 (99.6%) ECs in CTB5.1.[3]

(1) 不 愿意 发掘 培植 有 潜力 的 新 作家
not want look-for train have potential DE new writer
'(People) don't want to look for and train new writers who have potential.'

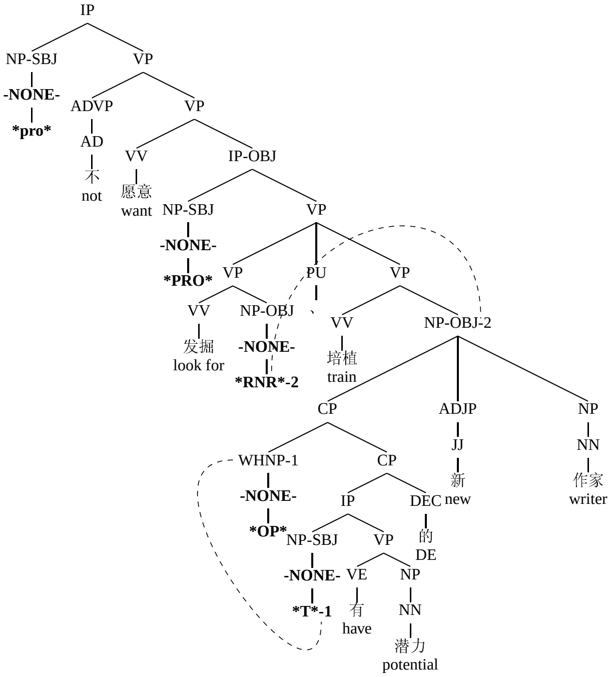

Figure 1: Example of non-local annotations in CTB, including dropped subject (*pro*), control subject (*PRO*), relative clause (*T*), and coordination (*RNR*).

According to their different linguistics properties, we divide the empty nodes listed in Table 1 into three major types: null relative pronouns, locally mediated dependencies, and long-distance dependencies.

Null Relative Pronouns (lines 2, 7) themselves are local dependencies, and thus are not coindexed with an antecedent. But they mediate non-local dependencies by functioning as antecedents for the dis-

[2] (Levy and Manning, 2004) is the only approach we are aware of that has been applied to both English and German.

[3] An extensive description of the types of empty categories and the use of coindexation in CTB can be found in Section VI of the bracketing guidelines.

	Antecedent	POS	Label	Count	Description

Table 1: The distribution of the most frequent types of empty categories and their antecedents in CTB5.1. The types with frequency less than 30 are ignored.

located constituent inside a relative clause.[4]

Locally Mediated Dependencies are non-local as they are projected through a third lexical item (such as a control or raising verb) which involves a dependency between two adjacent levels and they are therefore bounded. This type encompasses: (line 8) raising constructions, and short-bei constructions (passivisation); (line 3) control constructions, which includes two different types: a generic *PRO* with an arbitrary reading (approximately equals to unexpressed subjects of *to*-infinitive and gerund verbs in English); and a *PRO* with definite reference (subject or object control).[5]

Long-Distance Dependencies (LDDs) differ from locally mediated dependencies, in that the path linking the antecedent and trace might be unbounded (also called unbounded, long-range dependencies). LDDs include the following phenomena:

Wh-traces in relative clauses, where an argument (line 1) or adjunct (line 6) “moves” and is coindexed with the “extraction” site.

Topicalisation (lines 5, 11) is one of the typical LDDs in English, whereas in Chinese not all topics involve displacement, for instance (2).

(2) 北京 秋天 最 美
Beijing autumn most beautiful
‘Autumn is the most beautiful in Beijing.’

Coordination is divided into two groups: right node raising of an NP phrase which is an argument shared by the coordinate predicates (line 9); and the coordination of quantifier phrases (line 10) and verbal phrases (3), in which the antecedent and trace are both predicates and possibly take their own arguments or adjuncts.

(3) 我 和 他 分别 去 公司 和 *RNR* 医院
I and he respectively go to company and *RNR* hospital
‘I went to the company and he went to the hospital respectively.’

Pro-drop situations (line 4) are prominent in Chinese because subject and object are only semantically but not syntactically required. Nevertheless we also treat pro-drop as a long-distance dependency as in principle the dropped subjects can be determined from the general (often inter-sentential) context.

Table 2 gives a quantitative comparison of NLDs between Chinese data in CTB5.1 and English in Penn-II. The data reveals that: first, NLDs in Chinese are much more frequent than in English (by nearly 1.5 times); and moreover 69% are not explicitly linked to an antecedent, compared to 43% for English, due to the high prevalence of pro-drop in Chinese.

	# of sent	# of EC	# of EC/sent	# non-coindex	% non-coindex
Chinese	18,804	43,954	2.34	30,429	69.23
English	49,207	79,245	1.61	34,455	43.48

Table 2: Comparison of NLDs between Chinese data in CTB5.1 and English in Penn-II .

[4] Null relative pronouns used in the CTB annotation are to distinguish relative clauses in which an argument or adjunct of the embedded verb is “missing” from complement (appositive) clauses which do not involve non-local dependencies.

[5] However in this case the CTB annotation doesn’t coindex the locus (trace) with its controller (antecedent).

(4) 钱 我们 用 来 享乐
money we use to please
'Money, we use for pleasure.'

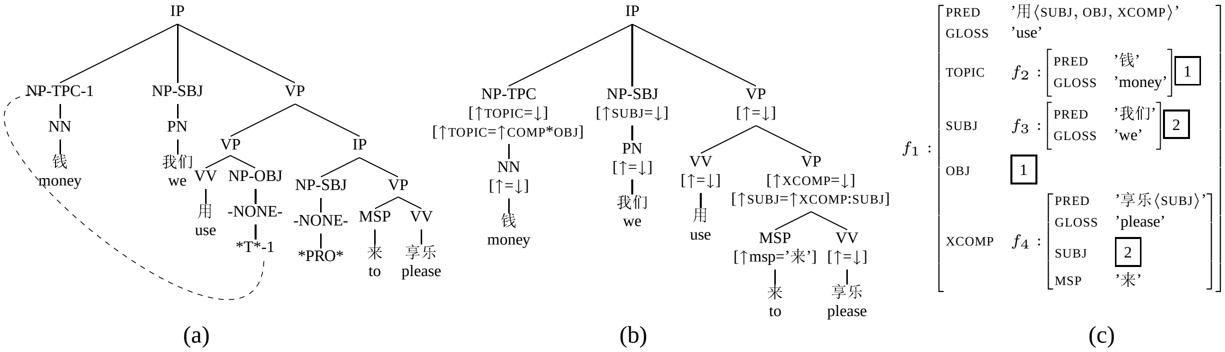

Figure 2: (a) the CTB tree; (b) LFG c-structure with functional equations; (c) corresponding f-structure. (↑) in the functional annotation refers to the f-structure associated with the mother node and (↓) to that of the local node.

3 NLD Recovery in LFG Approximations

3.1 Lexical Functional Grammar

Lexical Functional Grammar (Kaplan and Bresnan, 1982) is a constraint-based grammar formalism which minimally involves two levels of syntactic representation: c(onstituent)-structure and f(unctional)-structure. C-structure takes the form of CFG-trees and captures surface grammatical configurations. F-structure encodes more abstract grammatical functions (GFs) such as SUBJ(ect), OBJ(ect), COMP(lement), ADJ(unct) and TOPIC etc., in the form of Attribute Value Matrices which approximate to basic predicate-argument-adjunct structures or dependency relations. C-structures are related to f-structures by functional annotations (cf. Figure 2 (b) & (c)).

In LFG, non-local dependencies are captured at f-structure level in terms of reentrancies, indicated $\boxed{1}$ for the topicalisation and $\boxed{2}$ for the control construction in Figure 2(c) obviating the need for traces and coindexation in the c-structure (Figure 2(b)), unlike in CTB trees (Figure 2(a)). LFG uses functional uncertainty (FU) equations (regular expressions) to specify paths in f-structures between the trace and its antecedent. To account for the reentrancy $\boxed{1}$ in the f-structure, a FU equation of the form ↑TOPIC=↑COMP*OBJ is required (as the length of the dependency might be unbounded). The equation states that the value of the TOPIC attribute is token identical with the value of the final OBJ argument along a path through the immediately enclosing f-structure along zero or more COMP attributes.

In addition to FU equations, subcategorisation information is also a significant ingredient in LFG's account of non-local dependencies. Subcategorisation frames (subcat frames) specify the governable grammatical functions (i.e. arguments) required by a particular predicate. In Figure 2(c) each predicate in the f-structure is followed by its subcat frame.

3.2 F-Structure Based NLD Recovery

(Cahill et al., 2004) presented a NLD recovery algorithm operating at LFG f-structure for treebank-based LFG approximations. The method automatically converts Penn-II treebank trees with traces and coindexation into proper f-structures where traces and coindexation in treebank trees (Figure 2(a)) are represented as corresponding reentrances in f-structures (Figure 2(c)), and from the f-structures automatically extracts subcat frames by collecting all arguments of the local predicate at each level of the f-structures, and further acquires finite approximations of FU equations by extracting paths linking the reentracies occurring in the f-structures.

(Cahill et al., 2004)'s approach for English resolves three LDD types in parser output trees without traces and coindexation (Figure 2(b)), i.e. topicalisation (TOPIC), wh-movement in relative clauses (TOPIC_REL) and interrogatives (FOCUS). Given a set of subcat frames s for lemma w with probabilities $P(s|w)$, a set of paths p linking reentrancies conditioned on the triggering antecedent a (TOPIC, TOPIC_REL or FOCUS) with probabilities $P(p|a)$, the core algorithm recursively traverses an f-structure f to:

- find a TOPIC|TOPIC_REL|FOCUS:g pair;
- traverse f along path p to the sub-f-structure h;
- retrieve the local PRED:w at h, and insert g to h iff
  - * all GFs specified in the subcat frame s except g are present at h (completeness condition)
  - * no other governable GFs present at h are specified in s (coherence condition)
- rank resolution candidates according to the product of subcat frame and NLD path probabilities (Eq. 1).

$$P(s|w) \times P(p|a) \tag{1}$$

4 NLD Recovery Algorithm for Chinese

4.1 Automatic F-Structure Generation

Our NLD recovery is done at the level of LFG f-structures. Inspired by (Cahill et al., 2004; Burke et al., 2004), we have implemented an f-structure annotation algorithm to automatically obtain f-structures from CFG-trees in the CTB5.1. The f-structure annotation algorithm, described below, is applied both to the original CTB trees providing functional tags, traces and coindexation to generate the training corpus, and to the parser output trees without traces and coindexation to provide the f-structure input for NLD recovery.

1. The CFG-trees are head-lexicalised by head-finding rules similar to (Collins, 1999), adapted to CTB.
2. Each local subtree of depth one is partitioned by the head into left and right context. Left-right context rules exploiting configurational, categorial and CTB functional tag information are used to assign each left and right constituent with appropriate functional equations.
3. Empty nodes and coindexation in the CTB trees are automatically captured into corresponding reentrances at f-structure via functional equations.
4. All the functional equations are collected and then passed to a constraint solver to generate f-structures.

4.2 Adaptation to Chinese

(Cahill et al., 2004)'s algorithm (Section 3.2) only resolves certain NLDs with known types of antecedents (TOPIC, TOPIC_REL and FOCUS) at f-structures. However, as illustrated in Section 2, except for relative clauses, the antecedents in Chinese NLDs do not systematically correspond to types of grammatical function. Furthermore nearly 70% of all empty categories are not coindexed with an antecedent. In order to resolve all Chinese NLDs represented in the CTB, we modify and substantially extend the (Cahill et al., 2004) (henceforth C04 for short) algorithm as follows:

Given the set of subcat frames s for the word w, and a set of paths p for the trace t, the algorithm traverses the f-structure f to:

- predict a dislocated argument t at a sub-f-structure h by comparing the local PRED:w to w's subcat frames s
- t can be inserted at h if h together with t is complete and coherent relative to subcat frame s
- traverse f starting from t along the path p
- link t to it's antecedent a if p's ending GF a exists in a sub-f-structure within f; or leave t without an antecedent if an empty path for t exists

In the modified algorithm, we condition the probability of NLD path p (including the empty path without an antecedent) on the GF associated of the trace t rather than the antecedent a as in C04. The path probability $P(p|t)$ is estimated as:

$$P(p|t) = \frac{count(p,t)}{\sum_{i=1}^{n} count(p_i,t)} \tag{2}$$

In contrast even to English, Chinese has very little morphological information. As a result, every word in Chinese has a unique form regardless of its syntactic distribution. For this reason we use more syntactic features w_feats in addition to word form to discriminate between appropriate subcat frames s. For a given word w, w_feats include:

- w_pos: the part-of-speech of w
- w_gf: the grammatical function of w

$P(s|w, w\_feats)$ replaces C04's $P(s|w)$ as lexical subcat frame probability and is estimated as:

$$P(s|w, w\_feats) = \frac{count(s, w, w\_feats)}{\sum_{i=1}^{n} count(s_i, w, w\_feats)} \quad (3)$$

As more conditioning features may cause sever sparse-data problems, in order to increase the coverage of the automatically acquired subcat frames, the subcat frame frequencies $count(s, w, w\_feats)$ are smoothed by backing off to w's part-of-speech w_pos according to Eq. (4). $P(s|w\_pos)$ is estimated according to Eq. (5) and weighted by a parameter Θ. The lexical subcat frame probabilities are estimated from the smoothed frequencies as shown in Eq. (6).

$$\begin{aligned} count_{bk}(s, w, w\_feats) &= count(s, w, w\_feats) \quad (4) \\ &\quad + \Theta P(s|w\_pos) \\ P(s|w\_pos) &= \frac{count(s, w\_pos, w\_gf)}{\sum_{i=1}^{n} count(s_i, w\_pos, w\_gf)} \quad (5) \\ P_{bk}(s|w, w\_feats) &= \frac{count_{bk}(s, w, w\_feats)}{\sum_{i=1}^{n} count_{bk}(s_i, w, w\_feats)} \quad (6) \end{aligned}$$

Finally, NLD resolutions are ranked according to:

$$P_{bk}(s|w, w\_feats) \times \prod_{j=1}^{m} P(p|t_j) \quad (7)$$

As, apart from the maximum number of arguments in a subcat frame, there is no a priori limit on the number of dislocated arguments in a local f-structure, we rank resolutions with the product of the path probabilities of each (of m) missing argument(s).

4.3 A Hybrid Fine-Grained Strategy

As described in Section 2, there are three types of NLDs in the CTB, and their different linguistic properties may require fine-grained recovery strategies. Furthermore, as the NLD recovery method described in Section 4.2 is triggered by "missing" subcategorisable grammatical functions, a few cases of NLDs in which the trace is not an argument in the f-structure, e.g. an ADJUNCT or TOPIC in relative clauses or an null PRED in verbal coordination, can not be recovered by the algorithm. Table 3 shows the types of NLD that can be recovered by C04 and by the algorithm presented in Section 4.2. Table 3 shows that a hybrid methodology is required to resolve all types of NLDs in the CTB. The hybrid method involves four strategies:

- Applying a few simple heuristic rules to insert the empty PRED for coordinations and null relative pronouns for relative constructions. The former is done by comparing the part-of-speech of the local predicates and their arguments in each coordinate; and the latter is triggered by GF ADJUNCT_REL in our system.
- Inserting an empty node with GF SUBJ for short-bei construction, control and raising constructions, and relate it to the upper-level SUBJ or OBJ accordingly.
- Exploiting the C04 algorithm to resolve the wh-trace in relativisation, including ungovernable GFs TOPIC and ADJUNCT.
- Using our modified algorithm (Section 4.2) to resolve the remaining types, viz. long-distance dependencies in Chinese.

	Antecedent			Trace	
	Topic_Rel	Other	Null	Argument	Adjunct
C04	√			√	√
Ours	√	√	√	√	

Table 3: Comparison of the ability of NLD recovery for Chinese between C04 and our algorithm

5 Experiments and Evaluation

For all our experiments, we used the first 760 articles (chtb_001.fid to chtb_931.fid, 10,384 sentences) of CTB5.1, from which 75 double-annotated files (chtb_001.fid to chtb_043.fid and chtb_900.fid to chtb_931.fid, 1,046 sentences) were used as test data,[6] 75 files (chtb_306.fid to chtb_325.fid and chtb_400.fid to chtb_454.fid, 1,082 sentences) were held out as development data, while the other 610 files (8,256 sentences) were used as training data. Experiments were carried out on two different kinds of input: first on CTB gold standard trees stripped of all empty nodes and coindexation information; and

[6] The complete list of double-annotated files can be found in the documentation of CTB5.1.

second, on the output trees of Bikel's parser (Bikel, 2004).

The evaluation metric adopted by most previous work used the label and string position of the trace and its antecedent (Johnson, 2002). As pointed out by (Campbell, 2004), this metric is insensitive to the correct attachment of the EC into the parse tree, and more importantly it is not clear whether it adequately measures performance in predicate-argument structure recovery. Therefore, we use a predicate-argument based evaluation method instead. The NLD recovery is represented as a triple in the form of REL(PRED : loc, GF : loc), where REL is the relation between the dislocated GF and the PRED. In the evaluation for insertion of traces, the GF is represented by the empty category, and in the evaluation for antecedent recovery, the GF is realised by the predicate of the antecedent, e.g. OBJ(用/use:3, 钱/money:1) in Figure 2(c). The antecedent and PRED are both numbered with their string position in the input sentence. Precision, recall and f-score are calculated for the evaluation.

5.1 CTB-Based F-Structure and NLD Resources Acquisition

5.1.1 Automatically Acquired F-Structures

As described in Section 4.1, we automatically generate LFG f-structures from the CTB trees to obtain the training data and generate f-structures from the parser output trees, on which the NLDs will be recovered. To evaluate the performance of the automatic f-structure annotation algorithm, we randomly selected 200 sentences from the test set and manually annotated the f-structures to generate a gold standard. The evaluation metric is the same as for NLD recovery in terms of predicate-argument relations. Table 4 reports the results against the 200-sentence gold standard given the original CTB trees and trees output by Bikel's parser.

Dependencies	Precision	Recall	F-Score
CTB Trees	95.60	95.82	95.71
Parser Output	74.37	73.15	73.75

Table 4: Evaluation of f-structure annotation

5.1.2 Acquiring Subcat Frames and NLD Paths

From the automatically generated f-structure training data, we extract 144,119 different lexical subcat frames and 178 paths linking traces and antecedents for NLD recovery. Tables 5 & 6 show some examples of the automatically extracted subcat frames and NLD paths respectively.

5.2 The Basic Model

The basic algorithm described in Section 4.2 can be used to indiscriminately resolve almost all NLD types for Chinese including locally mediated dependencies with few exceptions (traces with modifier GFs, which accounts for about 1.5% of all NLDs in CTB5.1). Table 7 shows the results of the basic algorithm for trace insertion and antecedent recovery on both stripped CTB trees and parser output trees. For comparison, we implemented the C04 algorithm on our data and evaluated the result. Since the basic algorithm focus on argument traces, results for arguments only are given separately.

Table 7 shows that the C04 algorithm achieves a high precision but as expected a low recall due to its limitation to certain types of NLDs. By contrast, our basic algorithm scored higher recall but lower precision, which is understandable as the C04 algorithm identifies the trace given a known antecedent, whereas our algorithm tries to identify both the trace and antecedent. Compared to trace

Table 8: Breakdown of trace insertion and antecedent recovery results on stripped CTB trees for the hybrid model by major grammatical functions.

insertion, the general results for antecedent identification are rather poor. Examining the development data, we found that most recovery errors were due to wrongly treating missing SUBJs as a PRO (using empty NLD paths). Since the subject in Chinese has a very strong tendency to be omitted if it can be inferred from context, the empty NLD path (without any antecedent) has the greatest probability in all resolution paths conditioned on SUBJ, and prevents the SUBJ from finding a proper antecedent in certain cases. To test the effect of the empty path on SUBJ, we weighted non-empty paths for SUBJ so as to suppress the empty path. After testing on the development set, the optimal weight was found to be 1.9. The subject path constraint model shows a dramatic improvement of 12.9% and 8.1% for the overall result of antecedent recovery on CTB trees and parser output trees.

5.3 The Hybrid Fine-Grained Model

As proposed in Section 4.3, we implemented a more fine-grained strategy to capture specific linguistic properties of different NLD types in the CTB. We also combine our basic algorithm (Section 4.2) with (Cahill et al., 2004)'s algorithm in order to resolve the modifier-function traces. The two algorithms may conflict due to (i) inserting the same trace at the same site but related to different antecedents or (ii) resolving the same antecedent to different traces. We keep the traces inserted by the C04 algorithm and abandon those inserted by our algorithm in case of conflict, as the results in Section 5.2 suggest that C04 has a higher precision than ours. Table 8 reports the results of trace insertion and antecedent recovery, respectively, on stripped CTB trees, broken down by major GFs.

The fine-grained hybrid model allows us to recover NLDs with traces with modifier functions and, more importantly it is sensitive to particular linguistic properties of different NLD types. As the hybrid model separates the locally mediated dependencies from other long-distance dependencies, it increases the f-score by 8.7% for antecedent recovery compared with the basic model. Table 9 reports the results of the hybrid model on parser output trees, which shows an increase of 3.6% for antecedent recovery (compared with Table 7).

	Insertion			Recovery

overall	64.07	62.37	63.21	54.53	53.08	53.79

Table 9: Evaluation of hybrid model for trace insertion and antecedent recovery on parser output trees.

5.4 Better Training for Parser Output

Our experiments show that although our NLD recovery algorithm performs well on stripped CTB trees, it is sensitive to the noise in parser output trees, with a performance drop of about 30%. This is in contrast to English data, on which (Johnson, 2002) reports a drop of 7-9% moving from treebank trees to parser output trees. No doubt this is partially due to the poor performance of the parser on Chinese data. It is widely accepted that parsing Chinese is more difficult than parsing other more configurational or richer morphological languages, such as English.[7] Our NLD recovery algorithm runs on automatically generated LFG f-structures. The f-structure annotation algorithm is highly tailored to the CTB bracketing scheme (using configurational, categorial and functional tag information), and suffers considerably from errors produced by the parser. Table 4 shows that performance of the f-structure annotation decreases sharply (about 22%) for the parser output trees and this contributes to the eventual trace insertion and antecedent recovery performance drop.

Since the f-structures automatically generated from parser output trees are substantially different from those generated from the original CTB trees, our method to obtain the NLD resolution training data suffers from a serious drawback: the training data come from perfect CTB trees, whereas test data are derived from imperfect parser output trees. This constitutes a serious drawback for machine learning based approaches, such as ours: ideally, instances seen during training should be similar to unseen test data. To make training examples more similar to test instances, we reparse the training set to obtain better training data. To avoid running the parser on the training data, we carried out 10-fold-cross training, dividing the training data into 10 parts and parsing each part in turn with the parser trained on the remaining 9 parts. The reparsed training data are more similar to the test data than the original perfect CTB trees. We then converted both the reparsed training data and the original CTB trees into f-structures, and by comparing with the f-structures generated from the original CTB trees, we recovered the empty nodes and coindexation on the f-structures generated from the reparsed training data. We used parser output based f-structures to train our NLD recovery model and recovered NLDs for parser output trees from the test data. Table 10 presents the results for trace insertion and antecedent recovery on parser output trees using the improved training method, which shows a clear increase in precision and almost the same recall over the normal training (Table 9).

	Insertion			Recovery		
	Prec.	Rec.	F	Prec.	Rec.	F

6 Conclusion

We have presented an algorithm for recovering nonlocal dependencies for Chinese. Our method revises and considerably extends the approach of (Cahill et al., 2004) originally designed for English, and, to the best of our knowledge, is the first NLD recovery algorithm for Chinese. The evaluation shows that our algorithm considerably outperforms (Cahill et al., 2004)'s with respect to Chinese data.

In future work, we will refine and extend the conditioning features in our models to discriminate subcat frames and explore the possibilities to use the Chinese Propbank and Hownet to supplement our automatically acquired subcat frames. We will investigate ways of closing the gap between the performance of gold-standard and parer output trees, including improving parsing result for Chinese. We also plan to adapt other NLD recovery methods (Jijkoun and Rijke, 2004; Schmid, 2006) to Chinese and compare them with the current results.

Abstract

We present a simple history-based model for sentence generation from LFG f-structures, which improves on the accuracy of previous models by breaking down PCFG independence assumptions so that more f-structure conditioning context is used in the prediction of grammar rule expansions. In addition, we present work on experiments with named entities and other multi-word units, showing a statistically significant improvement of generation accuracy. Tested on section 23 of the Penn Wall Street Journal Treebank, the techniques described in this paper improve BLEU scores from 66.52 to 68.82, and coverage from 98.18% to 99.96%.

1 Introduction

Sentence generation, or surface realisation, is the task of generating meaningful, grammatically correct and fluent text from some abstract semantic or syntactic representation of the sentence. It is an important and growing field of natural language processing with applications in areas such as transfer-based machine translation (Riezler and Maxwell, 2006) and sentence condensation (Riezler et al., 2003). While recent work on generation in restricted domains, such as (Belz, 2007), has shown promising results there remains much room for improvement particularly for broad coverage and robust generators, like those of Nakanishi et al. (2005) and Cahill and van Genabith (2006), which do not rely on handcrafted grammars and thus can easily be ported to new languages.

This paper is concerned with sentence generation from Lexical-Functional Grammar (LFG) f-structures (Kaplan, 1995). We present improvements in previous LFG-based generation models firstly by breaking down PCFG independence assumptions so that more f-structure conditioning context is included when predicting grammar rule expansions. This history-based approach has worked well in parsing (Collins, 1999; Charniak, 2000) and we show that it also improves PCFG-based generation.

We also present work on utilising named entities and other multi-word units to improve generation results for both accuracy and coverage. There has been a limited amount of exploration into the use of multi-word units in probabilistic parsing, for example in (Kaplan and King, 2003) (LFG parsing) and (Nivre and Nilsson, 2004) (dependency parsing). We are not aware of any similar work on generation. In the LFG-based generation algorithm presented by Cahill and van Genabith (2006) complex named entities (i.e. those consisting of more than one word token) and other multi-word units can be fragmented in the surface realization. We show that the identification of such units may be used as a simple measure to constrain the generation model's output.

We take the generator of (Cahill and van Genabith, 2006) as our baseline generator. When tested on f-structures for all sentences from Section 23 of the Penn Wall Street Journal (WSJ) treebank (Mar-

cus et al., 1993), the techniques described in this paper improve BLEU score from 66.52 to 68.82. In addition, coverage is increased from 98.18% to almost 100% (99.96%).

The remainder of the paper is structured as follows: in Section 2 we review related work on statistical sentence generation. Section 3 describes the baseline generation model and in Section 4 we show how the new history-based model improves over the baseline. In Section 5 we describe the source of the multi-word units (MWU) used in our experiments and the various techniques we employ to make use of these MWUs in the generation process. Section 6 gives experimental details and results.

2 Related Work on Statistical Generation

In (statistical) generators, sentences are generated from an abstract linguistic encoding via the application of grammar rules. These rules can be handcrafted grammar rules, such as those of (Langkilde-Geary, 2002; Carroll and Oepen, 2005), created semi-automatically (Belz, 2007) or, alternatively, extracted fully automatically from treebanks (Bangalore and Rambow, 2000; Nakanishi et al., 2005; Cahill and van Genabith, 2006).

Insofar as it is a broad coverage generator, which has been trained and tested on sections of the WSJ corpus, our generator is closer to the generators of (Bangalore and Rambow, 2000; Langkilde-Geary, 2002; Nakanishi et al., 2005) than to those designed for more restricted domains such as weather forecast (Belz, 2007) and air travel domains (Ratnaparkhi, 2000).

Another feature which characterises statistical generators is the probability model used to select the most probable sentence from among the space of all possible sentences licensed by the grammar. One generation technique is to first generate all possible sentences, storing them in a word lattice (Langkilde and Knight, 1998) or, alternatively, a generation forest, a packed represention of alternate trees proposed by the generator (Langkilde, 2000), and then select the most probable sequence of words via an n-gram language model.

Increasingly syntax-based information is being incorporated directly into the generation model. For example, Carroll and Oepen (2005) describe a sentence realisation process which uses a hand-crafted HPSG grammar to generate a generation forest. A selective unpacking algorithm allows the extraction of an *n*-best list of realisations where realisation ranking is based on a maximum entropy model. This unpacking algorithm is used in (Velldal and Oepen, 2005) to rank realisations with features defined over HPSG derivation trees. They achieved the best results when combining the tree-based model with an *n*-gram language model.

Nakanishi et al. (2005) describe a treebank-extracted HPSG-based chart generator. Importing techniques developed for HPSG parsing, they apply a log linear model to a packed representation of all alternative derivation trees for a given input. They found that a model which included syntactic information outperformed a bigram model as well as a combination of bigram and syntax model.

The probability model described in this paper also incorporates syntactic information, however, unlike the discriminative HPSG models just described, it is a generative history- and PCFG-based model. While Belz (2007) and Humphreys et al. (2001) mention the use of contextual features for the rules in their generation models, they do not provide details nor do they provide a formal probability model. To the best of our knowledge this is the first paper providing a probabilistic generative, history-based generation model.

3 Surface Realisation from f-Structures

Cahill and van Genabith (2006) present a probabilistic surface generation model for LFG (Kaplan, 1995). LFG is a constraint-based theory of grammar, which analyses strings in terms of c(onstituency)-structure and f(unctional)-structure (Figure 1). C-structure is defined in terms of CFGs, and f-structures are recursive attribute-value matrices which represent abstract syntactic functions (such as SUBJect, OBJect, OBLique, COMPlement (sentential), ADJ(N)unct), agreement, control, long-distance dependencies and some semantic information (e.g. tense, aspect).

C-structures and f-structures are related in a projection architecture in terms of a piecewise correspondence ϕ.[1] The correspondence is indicated in

[1] Our formalisation follows (Kaplan, 1995).

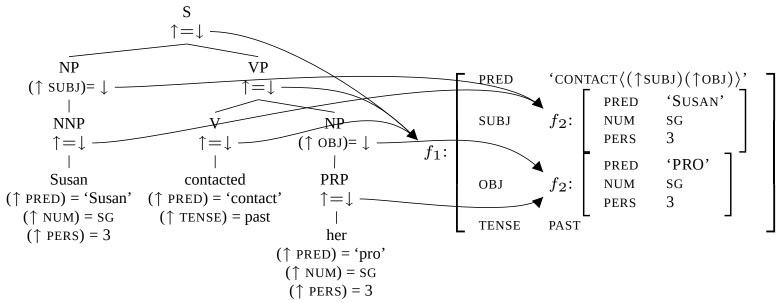

Figure 1: C- and f-structures with ϕ links for the sentence *Susan contacted her.*

terms of the curvy arrows pointing from c-structure nodes to f-structure components in Figure 1. Given a c-structure node n_i, the corresponding f-structure component f_j is $\phi(n_i)$. F-structures and the c-structure/f-structure correspondence are described in terms of functional annotations on c-structure nodes (CFG grammar rules). An equation of the form (↑F) = ↓ states that the f-structure associated with the mother of the current c-structure node (↑) has an attribute (grammatical function) (F), whose value is the f-structure of the current node (↓). The up-arrows and down-arrows are shorthand for $\phi(\mathrm{M}(n_i)) = \phi(n_i)$ where n_i is the c-structure node annotated with the equation.[2]

$$Tree_{best} := \text{argmax}_{\textit{Tree}} P(\textit{Tree}|\textit{F-Str}) \quad (1)$$

$$P(Tree|\textit{F-Str}) := \prod_{\substack{X \to Y \; in \; Tree \\ Feats = \{a_i | \exists v_j (\phi(X)) a_i = v_j\}}} P(X \to Y | X, Feats) \quad (2)$$

The generation model of (Cahill and van Genabith, 2006) maximises the probability of a tree given an f-structure (Eqn. 1), and the string generated is the yield of the highest probability tree. The generation process is guided by *purely* local information in the input f-structure: f-structure annotated CFG rules (LHS → RHS) are conditioned on their LHSs and on the set of features/attributes *Feats* = $\{a_i | \exists v_j \phi(\text{LHS}) a_i = v_j\}$[3] ϕ-linked to the LHS (Eqn. 2). Table 1 shows a generation grammar rule and conditioning features extracted from the example in Figure 1. The probability of a tree is decomposed into the product of the probabilities of the f-structure annotated rules (conditioned on the LHS and local *Feats*) contributing to the tree. Conditional probabilities are estimated using maximum likelihood estimation.

grammar rule	local conditioning features
S(↑=↓)⟶ NP(↑SUBJ=↓) VP(↑=↓)	S(↑=↓), {SUBJ,OBJ,PRED,TENSE}

Table 1: Example grammar rule (from Figure 1).

Cahill and van Genabith (2006) note that conditioning f-structure annotated generation rules on local features (Eqn. 2) can sometimes cause the model to make inappropriate choices. Consider the following scenario where in addition to the c-/f-structure in Figure 1, the training set contains the c-/f-structure displayed in Figure 2.

From Figures 1 and 2, the model learns (among others) the generation rules and conditional probabilities displayed in Tables 2 and 3.

F-Struct Feats	Grammar Rules	Prob
{SUBJ, OBJ, PRED}	S(↑=↓) ⟶ NP(↑SUBJ=↓) VP(↑=↓)	1
{SUBJ, OBJ, PRED}	VP(↑=↓) ⟶ V(↑=↓) NP(↑OBJ=↓)	1
{NUM, PER, GEN}	NP(↑SUBJ=↓) ⟶ NNP(↑=↓)	0.5
{NUM, PER, GEN}	NP(↑SUBJ=↓) ⟶ PRP(↑=↓)	0.5
{NUM, PER, GEN}	NP(↑OBJ=↓) ⟶ PRP(↑=↓)	1

Table 2: A sample of internal grammar rules extracted from Figures 1 and 2.

Given the input f-structure (for `She accepted`) in Figure 3, (and assuming suitable generation rules for intransitive VPs and `accepted`) the model would produce the inappropriate highest probability tree of Figure 4 with an incorrect case for the pronoun in subject position.

[2] M is the mother function on CFG tree nodes.

[3] In words, *Feats* is the set of top level features/attributes (those attributes a_i for which there is a value v_i) of the f-structure ϕ linked to the LHS.

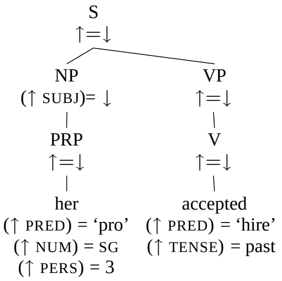

Figure 4: Inappropriate output: *her accepted.*

F-Struct Feats	Grammar Rules
{PRED=PRO,NUM=SG PER=3, GEN=FEM}	PRP-nom(↑=↓) ⟶ she
{PRED=PRO,NUM=SG PER=3, GEN=FEM}	PRP-acc(↑=↓) ⟶ her

Table 5: Lexical item rules with case markings

To solve the problem, Cahill and van Genabith (2006) apply an automatic generation grammar transformation to their training data: they automatically label CFG nodes with additional case information and the model now learns the new improved generation rules of Tables 4 and 5. Note how the additional case labelling subverts the problematic independence assumptions of the probability model and communicates the fact that a subject NP has to be realised as nominative case from the *S* ⟶ *NP-nom VP* production, via the intermediate *NP-nom* ⟶ *PRP-nom*, down to the lexical production *PRP-nom* ⟶ *she*. The labelling guarantees that, given the example f-structure in Figure 3, the model generates the correct string `she accepted`.

F-Struct Feats	Grammar Rules
{SUBJ, OBJ, PRED}	S(↑=↓) ⟶ NP-nom(↑SUBJ=↓) VP(↑=↓)
{SUBJ, OBJ, PRED}	VP(↑=↓) ⟶ V(↑=↓) NP-acc(↑OBJ=↓)
{NUM, PER, GEN}	NP-nom(↑SUBJ=↓) ⟶ PRP-nom(↑=↓)
{NUM, PER, GEN}	NP-nom(↑SUBJ=↓) ⟶ NNP-nom(↑=↓)
{NUM, PER, GEN}	NP-acc(↑OBJ=↓) ⟶ PRP-acc(↑=↓)

4 A History-Based Generation Model

The automatic generation grammar transform presented in (Cahill and van Genabith, 2006) provides a solution to coarse-grained and (in fact) inappropriate independence assumptions in the basic generation model. However, there is a sense in which the proposed cure improves on the symptoms, but not the cause of the problem: it weakens independence assumptions by multiplying and hence increasing the specificity of conditioning CFG category labels. There is another option available to us, and that is the option we will explore in this paper: instead of applying a generation grammar transform, we will improve the f-structure-based conditioning of the generation rule probabilities. In the original model, rules are conditioned on *purely local* f-structure context: the set of features/attributes ϕ-linked to the LHS of a grammar rule. As a direct consequence of this, the conditioning (and hence the model) cannot not distinguish between NP, PRP and NNP rules appropriate to e.g. subject (SUBJ) or object contexts (OBJ) in a given input f-structure. However, the required information can easily be incorporated into the generation model by uniformly conditioning generation rules on their *parent* (*mother*) grammatical function, in addition to the local ϕ-linked feature set. This additional conditioning has the effect of making the choice of generation rules sensitive to the *history* of the generation process, and, we argue, provides a simpler, more uniform, general, intuitive and natural probabilistic generation model obviating the need for CFG-grammar transforms in the original proposal of (Cahill and van Genabith, 2006).

In the new model, each generation rule is now conditioned on the LHS rule CFG category, the set of features ϕ-linked to LHS *and* the parent grammatical function of the f-structure ϕ-linked to LHS. In a given c-/f-structure pair, for a CFG node n, the parent grammatical function of the f-structure ϕ-linked to n is that grammatical function GF, which, if we take the f-structure ϕ-linked to the mother M(n), and apply it to GF, returns the f-structure ϕ-linked to n: $(\phi(\mathrm{M}(n))\mathrm{GF}) = \phi(n)$.

The basic idea is best explained by way of an example. Consider again Figure 1. The mother grammatical function of the f-structure f_2 associated with node NP(↑SUBJ=↓) and its daughter NNP(↑=↓) (via the ↑=↓ functional annotation) is SUBJ, as $(\phi(\mathrm{M}(n_2))\mathrm{SUBJ}) = \phi(n_2)$, or equivalently $(f_1\mathrm{SUBJ}) = f_2$.

Given Figures 1 and 2 as training set, the improved model learns the generation rules (the mother grammatical function of the outermost f-structure is assumed to be a dummy TOP grammatical function) of Tables 6 and 7.

F-Struct Feats	Grammar Rules
{SUBJ, OBJ, PRED, **TOP**}	S(↑=↓) → NP(↑SUBJ=↓) VP(↑=↓)
{SUBJ, OBJ, PRED, **TOP**}	VP(↑=↓) → V(↑=↓) NP(↑OBJ=↓)
{NUM, PER, GEN, **SUBJ**}	NP(↑SUBJ=↓) → PRP(↑=↓)
{NUM, PER, GEN, **OBJ**}	NP(↑OBJ=↓) → PRP(↑=↓)
{NUM, PER, GEN, **SUBJ**}	NP(↑SUBJ=↓) → NNP(↑=↓)

Table 6: Grammar rules with extra feature extracted from F-Structures.

Note, that for our example the effect of the uniform additional conditioning on mother grammatical function has the same effect as the generation grammar transform of (Cahill and van Genabith, 2006), but without the need for the grammar transform. Given the input f-structure in Figure 3, the model will generate the correct string `she accepted`. In addition, uniform conditioning on mother grammatical function is more general than the case-phenomena specific generation grammar transform of (Cahill and van Genabith, 2006), in that it applies to each and every sub-part of a recursive input f-structure driving generation, making available relevant generation history (context) to guide local generation decisions.

F-Struct Feats	Grammar Rules
{PRED=PRO,NUM=SG PER=3, GEN=FEM, **SUBJ**}	PRP(↑=↓) → she
{PRED=PRO,NUM=SG PER=3, GEN=FEM, **OBJ**}	PRP(↑=↓) → her

Table 7: Lexical item rules.

The new history-based probabilistic generation model is defined as:

$$P(Tree|\textit{F-Str}) := \prod_{\substack{X \to Y \; in \; Tree \\ Feats = \{a_i | \exists v_j (\phi(X))a_i = v_j\} \\ (\phi(\mathrm{M}(X)))\mathbf{GF} = \phi(X)}} P(X \to Y | X, Feats, \mathbf{GF}) \tag{3}$$

Note that the new conditioning feature, the f-structure mother grammatical function, GF, is available from structure previously generated in the c-structure tree. As such, it is part of the *history* of the tree, i.e. it has already been generated in the top-down derivation of the tree. In this way, the generation model resembles history-based models for parsing (Black et al., 1992; Collins, 1999; Charniak, 2000). Unlike, say, the parent annotation for parsing of (Johnson, 1998) the parent GF feature for a particular node expansion is not merely extracted from the parent node in the c-structure tree, but is sometimes extracted from an ancestor node further up the c-structure tree via intervening ↑=↓ functional annotations.

Section 6 provides evaluation results for the new model on section 23 of the Penn treebank.

5 Multi-Word Units

In another effort to improve generator accuracy over the baseline model we explored the use of multi-word units in generation. We expect that the identification of MWUs may be useful in imposing word-order constraints and reducing the complexity of the generation task. Take, for example, the following

$$\begin{bmatrix} \textsc{app} & \begin{bmatrix} \textsc{adjunct} & \begin{bmatrix} \textsc{pred} & \text{`New'} \\ \textsc{num} & \text{sg} \\ \textsc{pers} & 3 \end{bmatrix} \\ \textsc{pred}\ \text{`York'} & \\ \textsc{num}\ \text{sg} & \\ \textsc{pers}\ 3 & \end{bmatrix} \end{bmatrix} \begin{bmatrix} \textsc{app} & \begin{bmatrix} \textsc{pred} & \text{`New\_York'} \\ \textsc{num} & \text{sg} \\ \textsc{pers} & 3 \end{bmatrix} \end{bmatrix} \begin{bmatrix} \textsc{app} & \begin{bmatrix} \textsc{adjunct} & \begin{bmatrix} \textsc{pred} & \text{`New'/NE1\_1} \\ \textsc{num} & \text{sg} \\ \textsc{pers} & 3 \end{bmatrix} \\ \textsc{pred}\ \text{`York'/NE1\_2} & \\ \textsc{num}\ \text{sg} & \\ \textsc{pers}\ 3 & \end{bmatrix} \end{bmatrix}$$

Figure 5: Three different f-structure formats. From left to right: the original f-structure format; the MWU chunk format; the MWU mark-up format.

two sentences which show the gold version of a sentence followed by the version of the sentence produced by the generator:

Gold *By this time , it was 4:30 a.m. in New York , and Mr. Smith fielded a call from a New York customer wanting an opinion on the British stock market , which had been having troubles of its own even before Friday 's New York market break .*

Test *By this time , in New York , it was 4:30 a.m. , and Mr. Smith fielded a call from* **New** *a customer* **York** *, wanting an opinion on the market British stock which had been having troubles of its own even before Friday 's New York market break .*

The gold version of the sentence contains a multi-word unit, *New York*, which appears fragmented in the generator output. If multi-word units were either treated as one token throughout the generation process, or, alternatively, if a constraint were imposed on the generator such that multi-word units were always generated in the correct order, then this should help improve generation accuracy. In Section 5.1 we describe the various techniques that were used to incorporate multi-word units into the generation process and in 5.2 we detail the different types and sources of multi-word unit used in the experiments. Section 6 provides evaluation results on test and development sets from the WSJ treebank.

5.1 Incorporating MWUs into the Generation Process

We carried out three types of experiment which, in different ways, enabled the generation process to respect the restrictions on word-order provided by multi-word units. For the first experiments (type 1), the WSJ treebank *training* and *test* data were altered so that multi-word units are concatenated into single words (for example, *New York* becomes *New_York*). As in (Cahill and van Genabith, 2006) f-structures are generated from the (now altered) treebank and from this data, along with the treebank trees, the PCFG-based grammar, which is used for training the generation model, is extracted. Similarly, the f-structures for the test and development sets are created from Penn Treebank trees which have been modified so that multi-word units form single units. The leftmost and middle f-structures in Figure 5 show an example of an original f-structure format and a named-entity chunked format, respectively. Strings output by the generator are then post-processed so that the concatenated word sequences are converted back into single words.

In the second experiment (type 2) only the *test* data was altered with no concatenation of MWUs carried out on the training data.

In the final experiments (type 3), instead of concatenating named entities, a constraint is introduced to the generation algorithm which penalises the generation of sequences of words which violate the internal word order of named entities. The input is marked-up in such a way that, although named entities are no longer chunked together to form single words, the algorithm can read which items are part of named entities. See the rightmost f-structure in Figure 5 for an example of an f-structure marked-up in this way. The tag *NE1_1*, for example, indicates that the sub-f-structure is part of a named identity with id number 1 and that the item corresponds to the first word of the named entity. The baseline generation algorithm, following Kay (1996)'s work on chart generation, already contains the hard constraint that when combining two chart edges they must cover disjoint sets of words. We added an additional constraint which prevents edges from being combined if this would result in the generation of a string which contained a named entity which was either incomplete or where the words in the named entity were generated in the wrong order.

5.2 Types of MWUs used in Experiments

We carry out experiments with multi-word units from three different sources. First, we use the output of the maximum entropy-based named entity recognition system of (Chieu and Ng, 2003). This system identifies four types of named entity: person, organisation, location, and miscellaneous. Additionally we use a dictionary of candidate multi-word expressions based on a list from the Stanford Multiword Expression Project[4]. Finally, we also carry out experiments with multi-word units extracted from the BBN Pronoun Coreference and Entity Type Corpus (Weischedel and Brunstein, 2005). This supplements the Penn WSJ treebank's one million words of syntax-annotated Wall Street Journal text with additional annotations of 23 named entity types, including nominal-type named entities such as person, organisation, location, etc. as well as numeric types such as date, time, quantity and money. Since the BBN corpus data is very comprehensive and is hand-annotated we take this be be a gold standard, representing an upper bound for any gains that might be made by identifying complex named entities in our experiments.[5] Table 8 gives examples of the various types of MWUs identified by the three sources.

For our purposes we are not concerned with the distinctions between different types of named entities; we are merely exploiting the fact that they may be treated as atomic units in the generation model. In all cases we disregard multi-word units that cross the original syntactic bracketing of the WSJ treebank. An overview of the various types of multi-word units used in our experiments is presented in Table 9.

MWU type	Examples
Names	*Martha Matthews* *Yoshio Hatakeyama*
Organisations	*Rolls-Royce Motor Cars Inc.* *Washington State University*
Locations	*New York City* *New Zealand*
Time expressions	*October 19th* *two years ago* *the 21st century*
Quantities	*$2.7 million to $3 million* *about 25 %* *60 mph*
Prepositional expressions	*in fact* *at the time* *on average*

Table 8: Examples of some of the types of MWU from the three different sources.

	average number	average length
(Chieu and Ng, 2003)	0.61	2.40
Stanford MWE Project	0.10	2.48
BBN Corpus	1.15	2.66

Table 9: Average number of MWUs per sentence and average MWU length in the WSJ treebank grouped by MWU source.

6 Experimental Evaluation

All experiments were carried out on the WSJ treebank with sections 02-21 for training, section 24 for development and section 23 for final test results. The LFG annotation algorithm of (Cahill et al., 2004) was used to produce the f-structures for development, test and training sets.

Table 10 shows the final results for section 23. For each test we present BLEU score results as well as String Edit Distance and coverage. We measure statistical significance using two different tests. First we use a bootstrap resampling method, popular for machine translation evaluations, to measure the significance of improvements in BLEU scores, with a resampling rate of 1000.[6] We also calculated the significance of an increase in String Edit Distance by carrying out a paired t-test on the mean difference of the String Edit Distance scores. In Table 10, $\gg$ means significant at level 0.005. $>$ means significant at level 0.05.

In Table 10, *Baseline* gives the results of the generation algorithm of (Cahill and van Genabith, 2006). *HB Model* refers to the improved model with the increased history context, as described in Section 4. The results, where for example the BLEU score rises from 66.52 to 67.24, show that even increasing the conditioning context by a limited

[4] mwe.stanford.edu

[5] Although it is possible there are other types of MWUs that may be more suitable to the task than the named entities identified by BBN, so further gains might be possible.

Table 10: Results on Section 23 for all sentence lengths.

amount increases the accuracy of the system significantly for both BLEU and String Edit Distance. In addition, coverage goes up from 98.18% to 99.88%.

+MWU Best Automatic displays our best results using automatically identified named entities. These were achieved using experiment type 2, described in Section 5, with the MWUs produced by (Chieu and Ng, 2003). Results displayed in Table 10 up to this point are cumulative. The final row in Table 10, *MWU BBN*, shows the best results with BBN MWUs: the history-based model with BBN multiword units incorporated in a type 1 experiment.

We now discuss the various MWU experiments in more detail. See Table 11 for a breakdown of the MWU experiment results on the development set, WSJ section 24. Our baseline for these experiments is the history-based generator presented in Section 4. For each experiment type described in Section 5.1 we ran three experiments, varying the source of MWUs. First, MWUs came from the automatic NE recogniser of (Chieu and Ng, 2003), then we added the MWUs from the Stanford list and finally we ran tests with MWUs extracted from the BBN corpus.

Our first set of experiments (type 1), where both training data and development set data were MWU-chunked, produced the worst results for the automatically chunked MWUs. BLEU score accuracy actually decreased for the automatically chunked MWU experiments. In an error analysis of type 1 experiments with (Chieu and Ng, 2003) concatenated MWUs, we inspected those sentences where accuracy had decreased from the baseline. We found that for over half (51.5%) of these sentences, the input f-structures contained no multi-word units at all. The problem for these sentences therefore lay with the probabilistic grammar extracted from the MWU-chunked training data. When the source of MWU for the type 1 experiments was the BBN, however, accuracy improved significantly over the baseline and the result is the highest accuracy achieved over all experiment types. One possible reason for the low accuracy scores in the type 1 experiments with the (Chieu and Ng, 2003) MWU chunked data could be noisy MWUs which negatively affect the grammar. For example, the named entity recogniser of (Chieu and Ng, 2003) achieves an accuracy of 88.3% on section 23 of the Penn Treebank.

In order to avoid changing the grammar through concatenation of MWU components (as in experiment type 1) and thus risking side-effects which cause some heretofore likely constructions become less likely and vice versa, we ran the next set of experiments (type 2) which leave the original grammar intact and alter the input f-structures only. These experiments were more successful overall and we achieved an improvement over the baseline for both BLEU and String Edit Distance scores with all MWU types. As can be seen from Table 11 the best score for automatically chunked MWUs are with the (Chieu and Ng, 2003) MWUs. Accuracy decreases marginally when we added the Stanford MWUs. In our final set of experiments (type 3) although the accuracy for all three types of MWUs improves over the baseline, accuracy is a little below the type 2 experiments.

It is difficult to compare sentence generators since the information contained in the input varies greatly between systems, systems are evaluated on different test sets and coverage also varies considerably. In order to compare our system with those of (Nakanishi et al., 2005) and (Langkilde-Geary, 2002) we report our best results with automatically acquired MWUs for sentences of ≤ 20 words in length on section 23: our system gets coverage of 100% and a BLEU score of 71.39. For the same test set Nakanishi et al. (2005) achieved coverage of 90.75 and a BLEU score of 77.33. Langkilde-Geary (2002) re-

		Section 24 (1346 sentences)

Table 11: Results on Section 24, all sentence lengths.

ports 82.7% coverage and a BLEU score of 75.7% on the same test set with the ‘permute,no dir’ type input. Langkilde-Geary (2002) report results for experiments with varying levels of linguistic detail in the input given to the generator. As with Nakanishi et al. (2005) we find the ‘permute,no dir’ type of input is most comparable to the level of information contained in our input f-structures. Finally, the symbolic generator of Callaway (2003) reports a Simple String Accuracy score of 88.84 and coverage of 98.7% on section 23 for all sentence lengths.

7 Conclusion and Future Work

We have presented techniques which improve the accuracy of an already state-of-art surface generation model. We found that a history-based model that increases conditioning context in PCFG style rules by simply including the grammatical function of the f-structure parent, improves generator accuracy. In the future we will experiment with increasing conditioning context further and using more sophisticated smoothing techniques to avoid sparse data problems when conditioning is increased.

We have also demonstrated that automatically acquired multi-word units can bring about moderate, but significant, improvements in generator accuracy. For automatically acquired MWUs, we found that this could best be achieved by concatenating input items when generating the f-structure input to the generator, while training the input generation grammar on the original (i.e. non-MWU concatenated) sections of the treebank. Relying on the BBN corpus as a source of multi-word units, we gave an upper bound to the potential usefulness of multi-word units in generation and showed that automatically acquired multi-word units, encouragingly, give results not far below the upper bound.

Abstract

Given multiple translations of the same source sentence, how to combine them to produce a translation that is better than any single system output? We propose a hierarchical system combination framework for machine translation. This framework integrates multiple MT systems' output at the word-, phrase- and sentence- levels. By boosting common word and phrase translation pairs, pruning unused phrases, and exploring decoding paths adopted by other MT systems, this framework achieves better translation quality with much less re-decoding time. The full sentence translation hypotheses from multiple systems are additionally selected based on N-gram language models trained on word/word-POS mixed stream, which further improves the translation quality. We consistently observed significant improvements on several test sets in multiple languages covering different genres.

1 Introduction

Many machine translation (MT) frameworks have been developed, including rule-based transfer MT, corpus-based MT (statistical MT and example-based MT), syntax-based MT and the hybrid, statistical MT augmented with syntactic structures. Different MT paradigms have their strengths and weaknesses. Systems adopting the same framework usually produce different translations for the same input, due to their differences in training data, preprocessing, alignment and decoding strategies. It is beneficial to design a framework that combines the decoding strategies of multiple systems as well as their outputs and produces translations better than any single system output. More recently, within the GALE[1] project, multiple MT systems have been developed in each consortium, thus system combination becomes more important.

Traditionally, system combination has been conducted in two ways: glass-box combination and black-box combination. In the glass-box combination, each MT system provides detailed decoding information, such as word and phrase translation pairs and decoding lattices. For example, in the multi-engine machine translation system (Nirenburg and Frederking, 1994), target language phrases from each system and their corresponding source phrases are recorded in a chart structure, together with their confidence scores. A chart-walk algorithm is used to select the best translation from the chart. To combine words and phrases from multiple systems, it is preferable that all the systems adopt similar preprocessing strategies.

In the black-box combination, individual MT systems only output their top-N translation hypotheses without decoding details. This is particularly appealing when combining the translation outputs from COTS MT systems. The final translation may be selected by voted language models and appropriate confidence rescaling schemes ((Tidhar and Kuss-

ner, 2000) and (Nomoto, 2004)). (Mellebeek et al., 2006) decomposes source sentences into meaningful constituents, translates them with component MT systems, then selects the best segment translation and combine them based on majority voting, language models and confidence scores.

(Jayaraman and Lavie, 2005) proposed another black-box system combination strategy. Given single top-one translation outputs from multiple MT systems, their approach reconstructs a phrase lattice by aligning words from different MT hypotheses. The alignment is based on the surface form of individual words, their stems (after morphology analysis) and part-of-speech (POS) tags. Aligned words are connected via edges. The algorithm finds the best alignment that minimizes the number of crossing edges. Finally the system generates a new translation by searching the lattice based on alignment information, each system's confidence scores and a language model score. (Matusov et al., 2006) and (Rosti et al., 2007) constructed a confusion network from multiple MT hypotheses, and a consensus translation is selected by redecoding the lattice with arc costs and confidence scores.

In this paper, we introduce our hierarchical system combination strategy. This approach allows combination on word, phrase and sentence levels. Similar to glass-box combination, each MT system provides detailed information about the translation process, such as which source word(s) generates which target word(s) in what order. Such information can be combined with existing word and phrase translation tables, and the augmented phrase table will be significantly pruned according to reliable MT hypotheses. We select an MT system to retranslate the test sentences with the refined models, and encourage search along decoding paths adopted by other MT systems. Thanks to the refined translation models, this approach produces better translations with a much shorter re-decoding time. As in the black-box combination, we select full sentence translation hypotheses from multiple system outputs based on n-gram language models. This hierarchical system combination strategy avoids problems like translation output alignment and confidence score normalization. It seamlessly integrates detailed decoding information and translation hypotheses from multiple MT engines, and produces better translations in an efficient manner. Empirical studies in a later section show that this algorithm improves MT quality by 2.4 BLEU point over the best baseline decoder, with a 1.4 TER reduction. We also observed consistent improvements on several evaluation test sets in multiple languages covering different genres by combining several state-of-the-art MT systems.

The rest of the paper is organized as follows: In section 2, we briefly introduce several baseline MT systems whose outputs are used in the system combination. In section 3, we present the proposed hierarchical system combination framework. We will describe word and phrase combination and pruning, decoding path imitation and sentence translation selection. We show our experimental results in section 4 and conclusions in section 5.

2 Baseline MT System Overview

In our experiments, we take the translation outputs from multiple MT systems. These include phrase-based statistical MT systems (Al-Onaizan and Papineni, 2006) (Block) and (Hewavitharana et al., 2005) (CMU_SMT) , a direct translation model (DTM) system (Ittycheriah and Roukos, 2007) and a hierarchical phrased-based MT system (Hiero) (Chiang, 2005). Different translation frameworks are adopted by different decoders: the DTM decoder combines different features (source words, morphemes and POS tags, target words and POS tags) in a maximum entropy framework. These features are integrated with a phrase translation table for flexible distortion model and word selection. The CMU_SMT decoder extracts testset-specific bilingual phrases on the fly with PESA algorithm. The Hiero system extracts context-free grammar rules for long range constituent reordering.

We select the IBM block decoder to re-translate the test set for glass-box system combination. This system is a multi-stack, multi-beam search decoder. Given a source sentence, the decoder tries to find the translation hypothesis with the minimum translation cost. The overall cost is the log-linear combination of different feature functions, such as translation model cost, language model cost, distortion cost and sentence length cost. The translation cost between a phrase translation pair (f, e) is defined as

$$TM(e, f) = \sum_i \lambda_i \phi(i) \quad (1)$$

where feature cost functions $\phi(i)$ includes:

$-\log p(f|e)$, a target-to-source word translation cost, calculated based on unnormalized IBM model1 cost (Brown et al., 1994);

$$p(f|e) = \prod_j \sum_i t(f_j|e_i) \quad (2)$$

where $t(f_j|e_i)$ is the word translation probabilities, estimated based on word alignment frequencies over all the training data. i and j are word positions in target and source phrases.

$-\log p(e|f)$, a source-to-target word translation cost, calculated similar to $-\log p(f|e)$;

$S(e, f)$, a phrase translation cost estimated according to their relative alignment frequency in the bilingual training data,

$$S(e, f) = -\log P(e|f) = -\log \frac{C(f, e)}{C(f)}. \quad (3)$$

λ's in Equation 1 are the weights of different feature functions, learned to maximize development set BLEU scores using a method similar to (Och, 2003).

The SMT system is trained with testset-specific training data. This is not cheating. Given a test set, from a large bilingual corpora we select parallel sentence pairs covering n-grams from source sentences. Phrase translation pairs are extracted from the subsampled alignments. This not only reduces the size of the phrase table, but also improves topic relevancy of the extracted phrase pairs. As a results, it improves both the efficiency and the performance of machine translation.

3 Hierarchical System Combination Framework

The overall system combination framework is shown in Figure 1. The source text is translated by multiple baseline MT systems. Each system produces both top-one translation hypothesis as well as phrase pairs and decoding path during translation. The information is shared through a common XML file format, as shown in Figure 2. It demonstrates how a source sentence is segmented into a sequence of phrases, the order and translation of each source phrase as well as the translation scores, and a vector of feature scores for the whole test sentence. Such XML files are generated by all the systems when they translate the source test set.

We collect phrase translation pairs from each decoder's output. Within each phrase pair, we identify word alignment and estimate word translation probabilities. We combine the testset-specific word translation model with a general model. We augment the baseline phrase table with phrase translation pairs extracted from system outputs, then prune the table with translation hypotheses. We retranslate the source text using the block decoder with updated word and phrase translation models. Additionally, to take advantage of flexible reordering strategies of other decoders, we develop a word order cost function to reinforce search along decoding paths adopted by other decoders. With the refined translation models and focused search space, the block decoder efficiently produces a better translation output. Finally, the sentence hypothesis selection module selects the best translation from each systems' top-one outputs based on language model scores. Note that the hypothesis selection module does not require detailed decoding information, thus can take in any MT systems' outputs.

3.1 Word Translation Combination

The baseline word translation model is too general for the given test set. Our goal is to construct a testset-specific word translation model, combine it with the general model to boost consensus word translations. Bilingual phrase translation pairs are read from each system-generated XML file. Word alignments are identified within a phrase pair based on IBM Model-1 probabilities. As the phrase pairs are typically short, word alignments are quite accurate. We collect word alignment counts from the whole test set translation, and estimate both source-to-target and target-to-source word translation probabilities. We combine such testset-specific translation model with the general model.

$$t''(e|f) = \gamma t'(e|f) + (1 - \gamma) t(e|f); \quad (4)$$

where $t'(e|f)$ is the testset-specific source-to-target word translation probability, and $t(e|f)$ is the prob-

ability from general model. γ is the linear combination weight, and is set according to the confidence on the quality of system outputs. In our experiments, we set γ to be 0.8. We combine both source-to-target and target-to-source word translation models, and update the word translation costs, $-\log p(e|f)$ and $-\log p(f|e)$, accordingly.

3.2 Phrase Translation Combination and Pruning

Phrase translation pairs can be combined in two different ways. We may collect and merge testset-specific phrase translation tables from each system, if they are available. Essentially, this is similar to combining the training data of multiple MT systems. The new phrase translation probability is calculated according to the updated phrase alignment frequencies:

$$P'(e|f) = \frac{C_b(f,e) + \sum \alpha_m C_m(f,e)}{C_b(f) + \sum \alpha_m C_m(f)}, \qquad (5)$$

where C_b is the phrase pair count from the baseline block decoder, and C_m is the count from other MT systems. α_m is a system-specific linear combination weight. If not all the phrase tables are available, we collect phrase translation pairs from system outputs, and merge them with C_b. In such case, we may adjust α to balance the small counts from system outputs and large counts from C_b.

The corresponding phrase translation cost is updated as

$$S'(e,f) = -\log P'(e|f). \qquad (6)$$

Another phrase combination strategy works on the sentence level. This strategy relies on the consensus of different MT systems when translating the same source sentence. It collects phrase translation pairs used by different MT systems to translate the same sentence. Similarly, it boosts common phrase pairs that are selected by multiple decoders.

$$S''(e,f) = \frac{\beta}{|C(f,e)|} \times S'(e,f), \qquad (7)$$

where β is a boosting factor, $0 < \beta \leq 1$. $|C(f,e)|$ is the number of systems that use phrase pair (f,e) to translate the input sentence. A phrase translation pair selected by multiple systems is more likely a good translation, thus costs less.

The combined phrase table contains multiple translations for each source phrase. Many of them are unlikely translations given the context. These phrase pairs produce low-quality partial hypotheses during hypothesis expansion, incur unnecessary model cost calculation and larger search space, and reduce the translation efficiency. More importantly, the translation probabilities of correct phrase pairs are reduced as some probability mass is distributed among incorrect phrase pairs. As a result, good phrase pairs may not be selected in the final translation.

Oracle experiments show that if we prune the phrase table and only keep phrases that appear in the reference translations, we can improve the translation quality by 10 BLEU points. This shows the potential gain by appropriate phrase pruning. We developed a phrase pruning technique based on self-training. This approach reinforces phrase translations learned from MT system output. Assuming we have reasonable first-pass translation outputs, we only keep phrase pairs whose target phrase is covered by existing system translations. These phrase pairs include those selected in the final translations, as well as their combinations or sub-phrases. As a result, the size of the phrase table is reduced by 80-90%, and the re-decoding time is reduced by 80%. Because correct phrase translations are assigned higher probabilities, it generates better translations with higher BLEU scores.

3.3 Decoding Path Imitation

Because of different reordering models, words in the source sentence can be translated in different orders. The block decoder has local reordering capability that allows source words within a given window to jump forward or backward with a certain cost. The DTM decoder takes similar reordering strategy, with some variants like dynamic window width depending on the POS tag of the current source word. The Hiero system allows for long range constituent reordering based on context-free grammar rules. To combine different reordering strategies from various decoders, we developed a reordering cost function that encourages search along decoding paths adopted by other decoders.

From each system's XML file, we identify the order of translating source words based on word alignment information. For example, given the following hypothesis path,

<p al="0-1"> izzat ibrahim </p> <p al="2-2"> receives </p> <p al="3-4"> an economic official </p> <p al="5-6"> in </p> <p al="7-7"> baghdad </p>

We find the source phrase containing words [0,1] is first translated into a target phrase "*izzat ibrahim*", which is followed by the translation from source word 2 to a single target word "*receives*", etc.. We identify the word alignment within the phrase translation pairs based on IBM model-1 scores. As a result, we get the following source word translation sequence from the above hypothesis (note: source word 5 is translated as NULL):

$0 < 1 < 2 < 4 < 3 < 6 < 7$

Such decoding sequence determines the translation order between any source word pairs, e.g., word 4 should be translated before word 3, 6 and 7. We collect such ordered word pairs from all system outputs' paths. When re-translating the source sentence, for each partially expanded decoding path, we compute the ratio of word pairs that satisfy such ordering constraints[2].

Specifically, given a partially expanded path $P = \{s_1 < s_2 < \cdots < s_m\}$, word pair $(s_i < s_j)$ implies s_i is translated before s_j. If word pair $(s_i < s_j)$ is covered by a full decoding path Q (from other system outputs), we denote the relationship as $(s_i < s_j) \in Q$.

For any ordered word pair $(s_i < s_j) \in P$, we define its matching ratio as the percentage of full decoding paths that cover it:

$$R(s_i < s_j) = \frac{|Q|}{N}, \{Q|(s_i < s_j) \in Q\} \qquad (8)$$

where N is the total number of full decoding paths.

We define the path matching cost function:

$$L(P) = -\log \frac{\sum_{\forall(s_i<s_j)\in P} R(s_i < s_j)}{\sum_{\forall(s_i<s_j)\in P} 1} \qquad (9)$$

The denominator is the total number of ordered word pairs in path P. As a result, partial paths are boosted if they take similar source word translation orders as other system outputs. This cost function is multiplied with a manually tuned model weight before integrating into the log-linear cost model framework.

[2] We set no constraints for source words that are translated into NULL.

3.4 Sentence Hypothesis Selection

The sentence hypothesis selection module only takes the final translation outputs from individual systems, including the output from the glass-box combination. For each input source sentence, it selects the "optimal" system output based on certain feature functions.

We experiment with two feature functions. One is a typical 5-gram word language model (LM). The optimal translation output E' is selected among the top-one hypothesis from all the systems according to their LM scores. Let e_i be a word in sentence E:

$$\begin{aligned} E' &= \arg\min_E -\log P_{5glm}(E) \quad (10) \\ &= \arg\min_E \sum_i -\log p(e_i|e_{i-4}^{i-1}), \end{aligned}$$

where e_{i-4}^{i-1} is the n-gram history, $(e_{i-4}, e_{i-3}, e_{i-2}, e_{i-1})$.

Another feature function is based on the 5-gram LM score calculated on the mixed stream of word and POS tags of the translation output. We run POS tagging on the translation hypotheses. We keep the word identities of top N frequent words (N=1000 in our experiments), and the remaining words are replaced with their POS tags. As a result, the mixed stream is like a skeleton of the original sentence, as shown in Figure 3.

With this model, the optimal translation output E^* is selected based on the following formula:

$$\begin{aligned} E^* &= \arg\min_E -\log P_{wplm}(E) \quad (11) \\ &= \arg\min_E \sum_i -\log p(T(e_i)|T(e)_{i-4}^{i-1}) \end{aligned}$$

where the mixed stream token $T(e) = e$ when $e \leq N$, and $T(e) = POS(e)$ when $e > N$. Similar to a class-based LM, this model is less prone to data sparseness problems.

4 Experiments

We experiment with different system combination strategies on the NIST 2003 Arabic-English MT evaluation test set. Testset-specific bilingual data are subsampled, which include 260K sentence pairs, 10.8M Arabic words and 13.5M English words. We report case-sensitive BLEU (Papineni et al., 2001) and TER (Snover et al., 2006) as the MT evaluation metrics. We evaluate the translation quality of different combination strategies:

	BLEUr4n4c	TER
sys1	0.5323	43.11
sys4	0.4742	46.35
Tstcom	0.5429	42.64
Tstcom+Sentcom	0.5466	42.32
Tstcom+Sentcom+Prune	0.5505	42.21

Table 1: Translation results with phrase combination and pruning.

- **WdCom:** Combine testset-specific word translation model with the baseline model, as described in section 3.1.
- **PhrCom:** Combine and prune phrase translation tables from all systems, as described in section 3.2. This include testset-specific phrase table combination (**Tstcom**), sentence level phrase combination (**Sentcom**) and phrase pruning based on translation hypotheses (**Prune**).
- **Path:** Encourage search along the decoding paths adopted by other systems via path matching cost function, as described in section 3.3.
- **SenSel:** Select whole sentence translation hypothesis among all systems' top-one outputs based on N-gram language models trained on word stream (**word**) and word-POS mixed stream(**wdpos).**

Table 1 shows the improvement by combining phrase tables from multiple MT systems using different combination strategies. We only show the highest and lowest baseline system scores. By combining testset-specific phrase translation tables (**Tstcom**), we achieved 1.0 BLEU improvement and 0.5 TER reduction. Sentence-level phrase combination and pruning additionally improve the BLEU score by 0.7 point and reduce TER by 0.4 percent.

Table 2 shows the improvement with different sentence translation hypothesis selection approaches. The word-based LM is trained with about 1.75G words from newswire text. A distributed

syscom	0.1386	69.23

Table 5: System combination results for Arabic-English web log translation.

large-scale language model architecture is developed to handle such large training corpora[3], as described in (Emami et al., 2007). The word-based LM shows both improvement in BLEU scores and error reduction in TER. On the other hand, even though the word-POS LM is trained with much less data (about 136M words), it improves BLEU score more effectively, though there is no change in TER.

Table 3 shows the improvements from hierarchical system combination strategy. We find that word-based translation combination improves the baseline block decoder by 0.16 BLEU point and reduce TER by 0.5 point. Phrase-based translation combination (including phrase table combination, sentence-level phrase combination and phrase pruning) further improves the BLEU score by 1.9 point (another 0.6 drop in TER). By encouraging the search along other decoder's decoding paths, we observed additional 0.15 BLEU improvement and 0.2 TER reduction. Finally, sentence translation hypothesis selection with word-based LM led to 0.2 BLEU point improvement and 0.16 point reduction in TER. To summarize, with the hierarchical system combination framework, we achieved 2.4 BLEU point improvement over the best baseline system, and reduce the TER by 1.4 point.

Table 4 shows the system combination results on Chinese-English newswire translation. The test data is NIST MT03 Chinese-English evaluation test set. In addition to the 4 baseline MT systems, we also add another phrase-based MT system (Lee et al., 2006). The system combination improves over the best baseline system by 2 BLEU points, and reduce the TER score by 1.6 percent. Thanks to the long range constituent reordering capability of different baseline systems, the path imitation improves the BLEU score by 0.4 point.

We consistently notice improved translation quality with system combination on unstructured text and speech translations, as shown in Table 5 and 6. With one reference translation, we notice 1.2 BLEU point improvement over the baseline block decoder (with 2.5 point TER reduction) on web log translation and about 2.1 point BLEU improvement (with 0.9 point TER reduction) on Broadcast News speech translation.

[3] The same LM is also used during first pass decoding by both the block and the DTM decoders.

5 Related Work

Many system combination research have been done recently. (Matusov et al., 2006) computes consensus translation by voting on a confusion network, which is created by pairwise word alignment of multiple baseline MT hypotheses. This is similar to the sentence- and word- level combinations in (Rosti et al., 2007), where TER is used to align multiple hypotheses. Both approaches adopt black-box combination strategy, as target translations are combined independent of source sentences. (Rosti et al., 2007) extracts phrase translation pairs in the phrase level combination. Our proposed method incorporates bilingual information from source and target sentences in a hierarchical framework: word, phrase and decoding path combinations. Such information proves very helpful in our experiments. We also developed a path matching cost function to encourage decoding path imitation, thus enable one decoder to take advantage of rich reordering models of other MT systems. We only combine top-one hypothesis from each system, and did not apply system confidence measure and minimum error rate training to tune system combination weights. This will be our future work.

6 Conclusion

Our hierarchical system combination strategy effectively integrates word and phrase translation combinations, decoding path imitation and sentence hypothesis selection from multiple MT systems. By boosting common word and phrase translation pairs and pruning unused ones, we obtain better translation quality with less re-decoding time. By imitating the decoding paths, we take advantage of various reordering schemes from different decoders. The sentence hypothesis selection based on N-gram language model further improves the translation quality. The effectiveness has been consistently proved in several empirical studies with test sets in different languages and covering different genres.

Abstract

This paper proposes a method using the existing Rule-based Machine Translation (RBMT) system as a black box to produce synthetic bilingual corpus, which will be used as training data for the Statistical Machine Translation (SMT) system. We use the existing RBMT system to translate the monolingual corpus into synthetic bilingual corpus. With the synthetic bilingual corpus, we can build an SMT system even if there is no real bilingual corpus. In our experiments using BLEU as a metric, the system achieves a relative improvement of 11.7% over the best RBMT system that is used to produce the synthetic bilingual corpora. We also interpolate the model trained on a real bilingual corpus and the models trained on the synthetic bilingual corpora. The interpolated model achieves an absolute improvement of 0.0245 BLEU score (13.1% relative) as compared with the individual model trained on the real bilingual corpus.

1 Introduction

Within the Machine Translation (MT) field, by far the most dominant paradigm is SMT, but many existing commercial systems are rule-based. In this research, we are interested in answering the question of whether the existing RBMT systems could be helpful to the development of an SMT system. To find the answer, let us first consider the following facts:

- Existing RBMT systems are usually provided as a black box. To make use of such systems, the most convenient way might be working on the translation results directly.
- SMT methods rely on bilingual corpus. As a data driven method, SMT usually needs large bilingual corpus as the training data.

Based on the above facts, in this paper we propose a method using the existing RBMT system as a black box to produce a synthetic bilingual corpus[1], which will be used as the training data for the SMT system.

For a given language pair, the monolingual corpus is usually much larger than the real bilingual corpus. We use the existing RBMT system to translate the monolingual corpus into synthetic bilingual corpus. Then, even if there is no real bilingual corpus, we can train an SMT system with the monolingual corpus and the synthetic bilingual corpus. If there exist *n* available RBMT systems for the desired language pair, we use the *n* systems to produce *n* synthetic bilingual corpora, and *n* translation models are trained with the *n* corpora respectively. We name such a model the *synthetic model*. An interpolated translation model is built by linear interpolating the *n* synthetic models. In our experiments using BLEU (Papineni et al., 2002) as the metric, the interpolated synthetic model achieves a relative improvement of 11.7% over the best RBMT system that is used to produce the synthetic bilingual corpora.

[1] In this paper, to be distinguished from the real bilingual corpus, the bilingual corpus generated by the RBMT system is called a synthetic bilingual corpus.

Proceedings of the 2007 Joint Conference on Empirical Methods in Natural Language Processing and Computational Natural Language Learning, pp. 287–295, Prague, June 2007.

Moreover, if a real bilingual corpus is available for the desired language pair, we build another translation model, which is named the *standard model*. Then we can build an *interpolated model* by interpolating the standard model and the synthetic models. Experimental results show that the interpolated model achieves an absolute improvement of 0.0245 BLEU score (13.1% relative) as compared with the standard model.

The remainder of this paper is organized as follows. In section 2 we summarize the related work. We then describe our method Using RBMT systems to produce bilingual corpus for SMT in section 3. Section 4 describes the resources used in the experiments. Section 5 presents the experiment result, followed by the discussion in section 6. Finally, we conclude and present the future work in section 7.

2 Related Work

In the MT field, by far the most dominant paradigm is SMT. SMT has evolved from the original word-based approach (Brown et al., 1993) into phrase-based approaches (Koehn et al., 2003; Och and Ney, 2004) and syntax-based approaches (Wu, 1997; Alshawi et al., 2000; Yamada and Knignt, 2001; Chiang, 2005). On the other hand, much important work continues to be carried out in Example-Based Machine Translation (EBMT) (Carl et al., 2005; Way and Gough, 2005), and many existing commercial systems are rule-based.

Although we are not aware of any previous attempt to use an existing RBMT system as a black box to produce synthetic bilingual training corpus for general purpose SMT systems, there exists a great deal of work on MT hybrids and Multi-Engine Machine Translation (MEMT).

Research into MT hybrids has increased over the last few years. Some research focused on the hybrid of various corpus-based MT methods, such as SMT and EBMT (Vogel and Ney, 2000; Marcu, 2001; Groves and Way, 2006; Menezes and Quirk, 2005). Others tried to exploit the advantages of both rule-based and corpus-based methods. Habash et al. (2006) built an Arabic-English generation-heavy MT system and boosted it with SMT components. METIS-II is a hybrid machine translation system, in which insights from SMT, EBMT, and RBMT are used (Vandeghinste et al., 2006). Seneff et al. (2006) combined an interlingual translation framework with phrase-based SMT for spoken language translation in a limited domain. They automatically generated a corpus of English-Chinese pairs from the same interlingual representation by parsing the English corpus and then paraphrasing each utterance into both English and Chinese.

Frederking and Nirenburg (1994) produced the first MEMT system by combining outputs from three different MT engines based on their knowledge of the inner workings of the engines. Nomoto (2004) used voted language models to select the best output string at sentence level. Some recent approaches to MEMT used word alignment techniques for comparison between the MT systems (Jayaraman and Lavie, 2005; Zaanen and Somers, 2005; Matusov et al. 2006). All the above MEMT systems operate on MT outputs for complete input sentences. Mellebeek et al. (2006) presented a different approach, using a recursive decomposition algorithm that produces simple chunks as input to the MT engines. A consensus translation is produced by combining the best chunk translation.

This paper uses RBMT outputs to improve the performance of SMT systems. Instead of RBMT outputs, other researchers have used SMT outputs to boost translation quality. Callision-Burch and Osborne (2003) used co-training to extend existing parallel corpora, wherein machine translations are selectively added to training corpora with multiple source texts. They also created training data for a language pair without a parallel corpus by using multiple source texts. Ueffing (2006) explored monolingual source-language data to improve an existing machine translation system via self-training. The source data is translated by a SMT system, and the reliable translations are automatically identified. Both of the methods improved translation quality.

3 Method

In this paper, we use the synthetic and real bilingual corpus to train the phrase-based translation models.

3.1 Phrase-Based Models

According to the translation model presented in (Koehn et al., 2003), given a source sentence f, the best target translation e_{best} can be obtained using the following model

$$\begin{aligned} \mathrm{e}_{\mathrm{best}} &= \arg\max_{\mathrm{e}} p(\mathrm{e} \mid \mathrm{f}) \\ &= \arg\max_{\mathrm{e}} p(\mathrm{f} \mid \mathrm{e}) p_{\mathrm{LM}}(\mathrm{e}) \omega^{\mathrm{length(e)}} \end{aligned} \quad (1)$$

Where the translation model $p(\mathrm{f} \mid \mathrm{e})$ can be decomposed into

$$\begin{aligned} & p(\overline{f}_1^I \mid \overline{e}_1^I) \\ &= \prod_{i=1}^{I} \phi(\overline{f}_i \mid \overline{e}_i) d(a_i - b_{i-1}) p_{\mathrm{w}}(\overline{f}_i \mid \overline{e}_i, a)^{\lambda} \end{aligned} \quad (2)$$

Where $\phi(\overline{f}_i \mid \overline{e}_i)$ is the phrase translation probability. a_i denotes the start position of the source phrase that was translated into the *i*th target phrase, and b_{i-1} denotes the end position of the source phrase translated into the (*i*-1)th target phrase. $d(a_i - b_{i-1})$ is the distortion probability. $p_{\mathrm{w}}(\overline{f}_i \mid \overline{e}_i, a)$ is the lexical weight, and λ is the strength of the lexical weight.

3.2 Interpolated Models

We train synthetic models with the synthetic bilingual corpus produced by the RBMT systems. We can also train a translation model, namely standard model, if a real bilingual corpus is available. In order to make full use of these two kinds of corpora, we conduct linear interpolation between them.

In this paper, the distortion probability in equation (2) is estimated during decoding, using the same method as described in Pharaoh (Koehn, 2004). For the phrase translation probability and lexical weight, we interpolate them as shown in (3) and (4).

$$\phi(\overline{f} \mid \overline{e}) = \sum_{i=0}^{n} \alpha_i \phi_i(\overline{f} \mid \overline{e}) \quad (3)$$

$$p_{\mathrm{w}}(\overline{f} \mid \overline{e}, a) = \sum_{i=0}^{n} \beta_i p_{\mathrm{w},i}(\overline{f} \mid \overline{e}, a) \quad (4)$$

Where $\phi_0(\overline{f} \mid \overline{e})$ and $p_{\mathrm{w},0}(\overline{f} \mid \overline{e}, a)$ denote the phrase translation probability and lexical weight trained with the real bilingual corpus, respectively. $\phi_i(\overline{f} \mid \overline{e})$ and $p_{\mathrm{w},i}(\overline{f} \mid \overline{e}, a)$ ($i = 1,...,n$) are the phrase translation probability and lexical weight estimated by *n* synthetic corpora produced by the RBMT systems. α_i and β_i are interpolation coefficients, ensuring $\sum_{i=0}^{n} \alpha_i = 1$ and $\sum_{i=0}^{n} \beta_i = 1$.

4 Resources Used in Experiments

4.1 Data

In the experiments, we take English-Chinese translation as a case study. The real bilingual corpus includes 494,149 English-Chinese bilingual sentence pairs. The monolingual English corpus is selected from the English Gigaword Second Edition, which is provided by Linguistic Data Consortium (LDC) (catalog number LDC2005T12). The selected monolingual corpus includes 1,087,651 sentences.

For language model training, we use part of the Chinese Gigaword Second Edition provided by LDC (catalog number LDC2005T14). We use 41,418 documents selected from the ZaoBao Newspaper and 992,261 documents from the XinHua News Agency to train the Chinese language model, amounting to 5,398,616 sentences.

The test set and the development set are from the corpora distributed for the 2005 HTRDP [2] evaluation of machine translation. It can be obtained from Chinese Linguistic Data Consortium (catalog number 2005-863-001). We use the same 494 sentences in the test set and 278 sentences in the development set. Each source sentence in the test set and the development set has 4 different references.

4.2 Tools

In this paper, we use two off-the-shelf commercial English to Chinese RBMT systems to produce the synthetic bilingual corpus.

We also need a trainer and a decoder to perform phrase-based SMT. We use Koehn's training scripts [3] to train the translation model, and the SRILM toolkit (Stolcke, 2002) to train language model. For the decoder, we use Pharaoh (Koehn, 2004). We run the decoder with its default settings (maximum phrase length 7) and then use Koehn's implementation of minimum error rate training (Och, 2003) to tune the feature weights on the de-

[2] The full name of HTRDP is National High Technology Research and Development Program of China, also named as 863 Program.

[3] It is located at http://www.statmt.org/wmt06/shared-task/baseline.html.

velopment set. The translation quality is evaluated using a well-established automatic measure: BLEU score (Papineni et al., 2002). We use the same method described in (Koehn and Monz, 2006) to perform the significance test.

5 Experimental Results

5.1 Results on Synthetic Corpus Only

With the monolingual English corpus and the English side of the real bilingual corpus, we translate them into Chinese using the two commercial RBMT systems and produce two synthetic bilingual corpora. With the corpora, we train two synthetic models as described in section 3.1. Based on the synthetic models, we also perform linear interpolation as shown in section 3.2, without the standard models. We tune the interpolation weights using the development set, and achieve the best performance when $\alpha_1 = 0.58$, $\alpha_2 = 0.42$, $\beta_1 = 0.58$, and $\beta_2 = 0.42$. The translation results on the test set are shown in Table 1. Synthetic model 1 and 2 are trained using the synthetic bilingual corpora produced by RBMT system 1 and RBMT system 2, respectively.

Method	BLEU
RBMT system 1	0.1681
RBMT system 2	0.1453
Synthetic Model 1	0.1644
Synthetic Model 2	0.1668
Interpolated Synthetic Model	0.1878

Table 1. Translation Results Using Synthetic Bilingual Corpus

From the results, it can be seen that the interpolated synthetic model obtains the best result, with an absolute improvement of the 0.0197 BLEU (11.7% relative) as compared with RBMT system 1, and 0.0425 BLEU (29.2% relative) as compared with RBMT system 2. It is very promising that our method can build an SMT system that significantly outperforms both of the two RBMT systems, using the synthetic bilingual corpus produced by two RBMT systems.

5.2 Results on Real and Synthetic Corpus

With the real bilingual corpus, we build a standard model. We interpolate the standard model with the two synthetic models built in section 5.1 to obtain interpolated models. The translation results are shown in Table 2. The interpolation coefficients are both for phrase table probabilities and lexical weights. They are also tuned using the development set.

From the results, it can be seen that all the three interpolated models perform not only better than the RBMT systems but also better than the SMT system trained on the real bilingual corpus. The interpolated model combining the standard model and the two synthetic models performs the best, achieving a statistically significant improvement of about 0.0245 BLEU (13.1% relative) as compared with the standard model with no synthetic corpus. It also achieves 26.1% and 45.8% relative improvement as compared with the two RBMT systems respectively. The results indicate that using the corpus produced by RBMT systems, the performance of the SMT system can be greatly improved. The results also indicate that the more the RBMT systems are used, the better the translation quality is.

Interpolation Coefficients			BLEU
Standard model	Synthetic Model 1	Synthetic Model 2	
1	—	—	0.1874
0.90	0.10	—	0.2056
0.86	—	0.14	0.2040
0.70	0.12	0.18	0.2119

Table 2. Translation Results Using Standard and Synthetic Bilingual Corpus

5.3 Effect of Synthetic Corpus Size

To explore the relationship between the translation quality and the scale of the synthetic bilingual corpus, we interpolate the standard model with the synthetic models trained with synthetic bilingual corpus of different sizes. In order to simplify the procedure, we only use RBMT system 1 to translate the 1,087,651 monolingual English sentences to produce the synthetic bilingual corpus.

We randomly select 20%, 40%, 60%, 80%, and 100% of the synthetic bilingual corpus to train different synthetic models. The translation results of the interpolated models are shown in Figure 1. The results indicate that the larger the synthetic bilingual corpus is, the better translation performance would be.

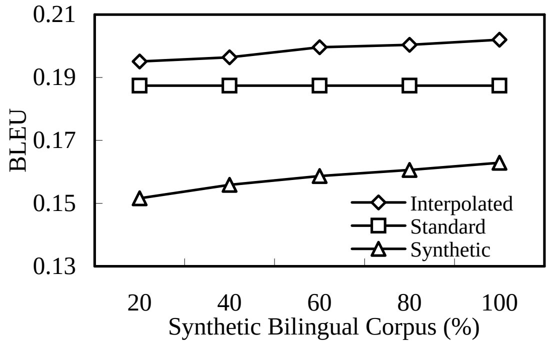

Figure 1. Comparison of Translation Results Using Synthetic Bilingual Corpus of Different Sizes

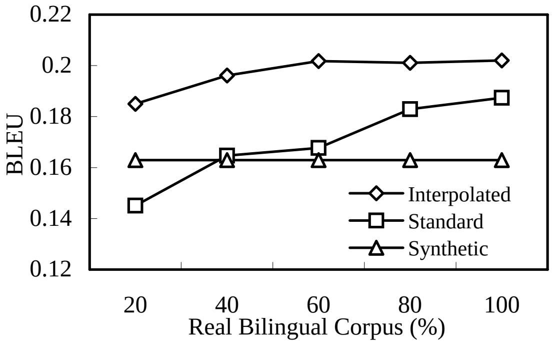

Figure 2. Comparison of Translation Results Using Real Bilingual Corpus of Different Sizes

5.4 Effect of Real Corpus Size

Another issue is the relationship between the SMT performance and the size of the real bilingual corpus. To train different standard models, we randomly build five corpora of different sizes, which contain 20%, 40%, 60%, 80%, and 100% sentence pairs of the real bilingual corpus, respectively. As to the synthetic model, we use the same synthetic model 1 that is described in section 5.1. Then we build five interpolated models by performing linear interpolation between the synthetic model and the five standard models respectively. The translation results are shown in Figure 2.

From the results, we can see that the larger the real bilingual corpus is, the better the performance of both standard models and interpolated models would be. The relative improvement of BLEU scores is up to 27.5% as compared with the corresponding standard models.

5.5 Results without Additional Monolingual Corpus

In all the above experiments, we use an additional English monolingual corpus to get more synthetic bilingual corpus. We are also interested in the results without the additional monolingual corpus. In such case, the only English monolingual corpus is the English side of the real bilingual corpus. We use this smaller size of monolingual corpus and the real bilingual corpus to conduct similar experiments as in section 5.2. The translation results are shown in Table 3.

From the results, it can be seen that our method works well even if no additional monolingual corpus is available. We achieve a statistically significant improvement of about 0.01 BLEU (5.2% relative) as compared with the standard model without using the synthetic corpus.

Interpolation Coefficients			BLEU
Standard model	Synthetic Model 1	Synthetic Model 2

Synthetic Model 2	357,489	881,921	9,216,760

Table 4. Numbers of Phrase Pairs

In order to further analyze the translation results, we examine the overlap and the difference among the phrase tables. The analytic results are shown in Table 4. More phrase pairs are extracted by the synthetic models, about twice by the synthetic model 1 in particular, than those extracted by the standard model. The overlap between each model is very low. For example, about 6% phrase pairs extracted by the standard model make appearance in both the standard model and the synthetic model 1. This also explains why the interpolated model outperforms that of the standard model in Table 3.

6 Discussion

6.1 Model Interpolation vs. Corpus Merge

In section 5, we make use of the real bilingual corpus and the synthetic bilingual corpora by performing model interpolation. Another available way is directly combining these two kinds of corpora to train a translation model, namely corpus merge. In order to compare these two methods, we use RBMT system 1 to translate the 1,087,651 monolingual English sentences to produce synthetic bilingual corpus. Then we train an SMT system with the combination of this synthetic bilingual corpus and the real bilingual corpus. The BLEU score of such system is 0.1887, while that of the model interpolation system is 0.2020. It indicates that the model interpolation method is significantly better than the corpus merge method.

6.2 Result Analysis

As discussed in Section 5.5, the number of the overlapped phrase pairs among the standard model and the synthetic models is very small. The newly added phrase pairs from the synthetic models can assist to improve the translation results of the interpolated model. In this section, we will use an example to further discuss the reason behind the improvement of the SMT system by using synthetic bilingual corpus. Table 5 shows an English sentence and its Chinese translations produced by different methods. And Figure 3 shows the phrase pairs used for translation. The results show that imperfect translations of RBMT systems can be also used to boost the performance of an SMT system.

	Phrase Pairs	Phrase Pairs Used	New Pairs Used
Standard Model	6,105,260	5,509	—
Interpolated Model	73,221,525	5,306	1993

Table 6. Statistics of Phrase Pairs

Further analysis is shown in Table 6. After adding the synthetic corpus produced by the RBMT systems, the interpolated model outperforms the standard models mainly for the following two reasons: (1) some new phrase pairs are added into the interpolated model. 37.6% phrase pairs (1993 out of 5306) are newly learned and used for translation. For example, the phrase pair "after-sale service <-> 售后服务 (shouhoufuwu)" is added; (2) The probability distribution of the phrase pairs is changed. For example, the probabilities of the two pairs "a brand name <-> 品牌 (pinpai)" and "and the creation of <-> 和 创造 (he chuangzao)" increase. The probabilities of the other two pairs "brand name <-> 品牌 (pinpai)" and "and the creation of a <-> 和 建立 (he jianli)" decrease. We found that 930 phrase pairs, which are also in the phrase table of the standard model, are used by the interpolated model for translation but not used by the standard model.

6.3 Human Evaluation

According to (Koehn and Monz, 2006; Callison-Burch et al., 2006), the RBMT systems are usually not adequately appreciated by BLEU. We also manually evaluated the RBMT systems and SMT systems in terms of both adequacy and fluency as defined in (Koehn and Monz, 2006). The evaluation results show that the SMT system with the interpolated model, which achieves the highest BLEU scores in Table 2, achieves slightly better adequacy and fluency scores than the two RBMT systems.

7 Conclusion and Future Work

We presented a method using the existing RBMT system as a black box to produce synthetic bilingual corpus, which was used as training data for the SMT system. We used the existing RBMT system to translate the monolingual corpus into a synthetic bilingual corpus. With the synthetic bilingual corpus, we could build an SMT system even if there is no real bilingual corpus. In our experiments using BLEU as the metric, such a system achieves a relative improvement of 11.7% over the best RBMT system that is used to produce the synthetic bilingual corpora. It indicates that using the existing RBMT systems to produce a synthetic bilingual corpus, we can build an SMT system that outperforms the existing RBMT systems.

We also interpolated the model trained on a real bilingual corpus and the models trained on the synthetic bilingual corpora, the interpolated model achieves an absolute improvement of 0.0245 BLEU score (13.1% relative) as compared with the individual model trained on the real bilingual corpus. It indicates that we can build a better SMT system by leveraging the real and the synthetic bilingual corpus.

Further result analysis shows that after adding the synthetic corpus produced by the RBMT systems, the interpolated model outperforms the standard models mainly because of two reasons: (1) some new phrase pairs are added to the interpolated model; (2) the probability distribution of the phrase pairs is changed.

In the future work, we will investigate the possibility of training a reverse SMT system with the RBMT systems. For example, we will investigate to train Chinese-to-English SMT system based on natural English and RBMT-generated synthetic Chinese.

Why doesn't EM find good HMM POS-taggers?

Abstract

This paper investigates why the HMMs estimated by Expectation-Maximization (EM) produce such poor results as Part-of-Speech (POS) taggers. We find that the HMMs estimated by EM generally assign a roughly equal number of word tokens to each hidden state, while the empirical distribution of tokens to POS tags is highly skewed. This motivates a Bayesian approach using a sparse prior to bias the estimator toward such a skewed distribution. We investigate Gibbs Sampling (GS) and Variational Bayes (VB) estimators and show that VB converges faster than GS for this task and that VB significantly improves 1-to-1 tagging accuracy over EM. We also show that EM does nearly as well as VB when the number of hidden HMM states is dramatically reduced. We also point out the high variance in all of these estimators, and that they require many more iterations to approach convergence than usually thought.

1 Introduction

It is well known that Expectation-Maximization (EM) performs poorly in unsupervised induction of linguistic structure (Carroll and Charniak, 1992; Merialdo, 1994; Klein, 2005; Smith, 2006). In retrospect one can certainly find reasons to explain this failure: after all, likelihood does not appear in the wide variety of linguistic tests proposed for identifying linguistic structure (Fromkin, 2001).

This paper focuses on unsupervised part-of-speech (POS) tagging, because it is perhaps the simplest linguistic induction task. We suggest that one reason for the apparent failure of EM for POS tagging is that it tends to assign relatively equal numbers of tokens to each hidden state, while the empirical distribution of POS tags is highly skewed, like many linguistic (and non-linguistic) phenomena (Mitzenmacher, 2003). We focus on first-order Hidden Markov Models (HMMs) in which the hidden state is interpreted as a POS tag, also known as bitag models.

In this setting we show that EM performs poorly when evaluated using a "1-to-1 accuracy" evaluation, where each POS tag corresponds to at most one hidden state, but is more competitive when evaluated using a "many-to-1 accuracy" evaluation, where several hidden states may correspond to the same POS tag. We explain this by observing that the distribution of hidden states to words proposed by the EM-estimated HMMs is relatively uniform, while the empirical distribution of POS tags is heavily skewed towards a few high-frequency tags. Based on this, we propose a Bayesian prior that biases the system toward more skewed distributions and show that this raises the 1-to-1 accuracy significantly. Finally, we show that a similar increase in accuracy can be achieved by reducing the number of hidden states in the models estimated by EM.

There is certainly much useful information that bitag HMMs models cannot capture. Toutanova et al. (2003) describe a wide variety of morphological and distributional features useful for POS tagging, and Clark (2003) proposes ways of incorporating some of these in an unsupervised tagging model. However, bitag models are rich enough to capture at least some distributional information (i.e., the tag

Proceedings of the 2007 Joint Conference on Empirical Methods in Natural Language Processing and Computational Natural Language Learning, pp. 296–305, Prague, June 2007.

for a word depends on the tags assigned to its neighbours). Moreover, more complex models add additional complicating factors that interact in ways still poorly understood; for example, smoothing is generally regarded as essential for higher-order HMMs, yet it is not clear how to integrate smoothing into unsupervised estimation procedures (Goodman, 2001; Wang and Schuurmans, 2005).

Most previous work exploiting unsupervised training data for inferring POS tagging models has focused on semi-supervised methods in the in which the learner is provided with a lexicon specifying the possible tags for each word (Merialdo, 1994; Smith and Eisner, 2005; Goldwater and Griffiths, 2007) or a small number of "prototypes" for each POS (Haghighi and Klein, 2006). In the context of semi-supervised learning using a tag lexicon, Wang and Schuurmans (2005) observe discrepencies between the empirical and estimated tag frequencies similar to those observed here, and show that constraining the estimation procedure to preserve the empirical frequencies improves tagging accuracy. (This approach cannot be used in an unsupervised setting since the empirical tag distribution is not available). However, as Banko and Moore (2004) point out, the accuracy achieved by these unsupervised methods depends strongly on the precise nature of the supervised training data (in their case, the ambiguity of the tag lexicon available to the system), which makes it more difficult to understand the behaviour of such systems.

2 Evaluation

All of the experiments described below have the same basic structure: an estimator is used to infer a bitag HMM from the unsupervised training corpus (the words of Penn Treebank (PTB) Wall Street Journal corpus (Marcus et al., 1993)), and then the resulting model is used to label each word of that corpus with one of the HMM's hidden states. This section describes how we evaluate how well these sequences of hidden states correspond to the gold-standard POS tags for the training corpus (here, the PTB POS tags). The chief difficulty is determining the correspondence between the hidden states and the gold-standard POS tags.

Perhaps the most straightforward method of establishing this correspondence is to deterministically map each hidden state to the POS tag it co-occurs most frequently with, and return the proportion of the resulting POS tags that are the same as the POS tags of the gold-standard corpus. We call this the *many-to-1 accuracy* of the hidden state sequence because several hidden states may map to the same POS tag (and some POS tags may not be mapped to by any hidden states at all).

As Clark (2003) points out, many-to-1 accuracy has several defects. If a system is permitted to posit an unbounded number of hidden states (which is not the case here) then it can achieve a perfect many-to-1 accuracy by placing every word token into its own unique state. Cross-validation, i.e., identifying the many-to-1 mapping and evaluating on different subsets of the data, would answer many of these objections. Haghighi and Klein (2006) propose constraining the mapping from hidden states to POS tags so that at most one hidden state maps to any POS tag. This mapping is found by greedily assigning hidden states to POS tags until either the hidden states or POS tags are exhausted (note that if the number of hidden states and POS tags differ, some will be unassigned). We call the accuracy of the POS sequence obtained using this map its *1-to-1 accuracy*.

Finally, several authors have proposed using information-theoretic measures of the divergence between the hidden state and POS tag sequences. Goldwater and Griffiths (2007) propose using the *Variation of Information* (VI) metric described by Meilă (2003). We regard the assignments of hidden states and POS tags to the words of the corpus as two different ways of clustering those words, and evaluate the conditional entropy of each clustering conditioned on the other. The VI is the sum of these conditional entropies. Specifically, given a corpus labeled with hidden states and POS tags, if $\tilde{p}(y), \tilde{p}(t)$ and $\tilde{p}(y,t)$ are the empirical probabilities of a hidden state y, a POS tag t, and the cooccurance of y and t respectively, then the mutual information I, entropies H and variation of information VI are defined as follows:

$$\begin{aligned}
H(Y) &= -\sum_y \tilde{p}(y) \log \tilde{p}(y) \\
H(T) &= -\sum_t \tilde{p}(t) \log \tilde{p}(t) \\
I(Y,T) &= \sum_{y,t} \tilde{p}(y,t) \log \frac{\tilde{p}(y,t)}{\tilde{p}(y)\tilde{p}(t)} \\
H(Y|T) &= H(Y) - I(Y,T)
\end{aligned}$$

$$
\begin{aligned}
H(T|Y) &= H(T) - I(Y,T) \\
VI(Y,T) &= H(Y|T) + H(T|Y)
\end{aligned}
$$

As Meilă (2003) shows, VI is a metric on the space of probability distributions whose value reflects the divergence between the two distributions, and only takes the value zero when the two distributions are identical.

3 Maximum Likelihood via Expectation-Maximization

There are several excellent textbook presentations of Hidden Markov Models and the Forward-Backward algorithm for Expectation-Maximization (Jelinek, 1997; Manning and Schütze, 1999; Bishop, 2006), so we do not cover them in detail here. Conceptually, a Hidden Markov Model generates a sequence of observations $\mathbf{x} = (x_0, \ldots, x_n)$ (here, the words of the corpus) by first using a Markov model to generate a sequence of hidden states $\mathbf{y} = (y_0, \ldots, y_n)$ (which will be mapped to POS tags during evaluation as described above) and then generating each word x_i conditioned on its corresponding state y_i. We insert endmarkers at the beginning and ending of the corpus and between sentence boundaries, and constrain the estimator to associate endmarkers with a state that never appears with any other observation type (this means each sentence can be processed independently by first-order HMMs; these endmarkers are ignored during evaluation).

In more detail, the HMM is specified by multinomials θ_y and ϕ_y for each hidden state y, where θ_y specifies the distribution over states following y and ϕ_y specifies the distribution over observations x given state y.

$$
\begin{array}{lcl}
y_i \mid y_{i-1} = y & \sim & \mathrm{Multi}(\theta_y) \\
x_i \mid y_i = y & \sim & \mathrm{Multi}(\phi_y)
\end{array}
\tag{1}
$$

We used the Forward-Backward algorithm to perform Expectation-Maximization, which is a procedure that iteratively re-estimates the model parameters (θ, ϕ), converging on a local maximum of the likelihood. Specifically, if the parameter estimate at time ℓ is $(\theta^{(\ell)}, \phi^{(\ell)})$, then the re-estimated parameters at time $\ell + 1$ are:

$$
\begin{aligned}
\theta^{(\ell+1)}_{y'|y} &= \mathrm{E}[n_{y',y}]/\mathrm{E}[n_y] \qquad (2) \\
\phi^{(\ell+1)}_{x|y} &= \mathrm{E}[n_{x,y}]/\mathrm{E}[n_y]
\end{aligned}
$$

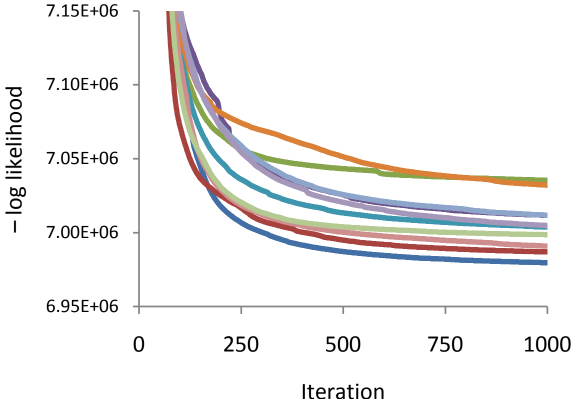

Figure 1: Variation in negative log likelihood with increasing iterations for 10 EM runs from different random starting points.

where $n_{x,y}$ is the number of times observation x occurs with state y, $n_{y',y}$ is the number of times state y' follows y and n_y is the number of occurences of state y; all expectations are taken with respect to the model $(\theta^{(\ell)}, \phi^{(\ell)})$.

We took care to implement this and the other algorithms used in this paper efficiently, since optimal performance was often only achieved after several hundred iterations. It is well-known that EM often takes a large number of iterations to converge in likelihood, and we found this here too, as shown in Figure 1. As that figure makes clear, likelihood is still increasing after several hundred iterations.

Perhaps more surprisingly, we often found dramatic changes in accuracy in the order of 5% occuring after several hundred iterations, so we ran 1,000 iterations of EM in all of the experiments described here; each run took approximately 2.5 days computation on a 3.6GHz Pentium 4. It's well-known that accuracy often decreases after the first few EM iterations (which we also observed); however in our experiments we found that performance improves again after 100 iterations and continues improving roughly monotonically. Figure 2 shows how 1-to-1 accuracy varies with iteration during 10 runs from different random starting points. Note that 1-to-1 accuracy at termination ranges from 0.38 to 0.45; a spread of 0.07.

We obtained a dramatic speedup by working directly with probabilities and rescaling after each observation to avoid underflow, rather than working with log probabilities (thanks to Yoshimasa Tsu-

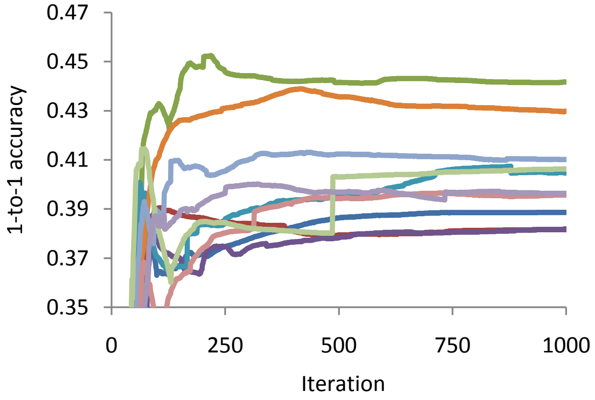

Figure 2: Variation in 1-to-1 accuracy with increasing iterations for 10 EM runs from different random starting points.

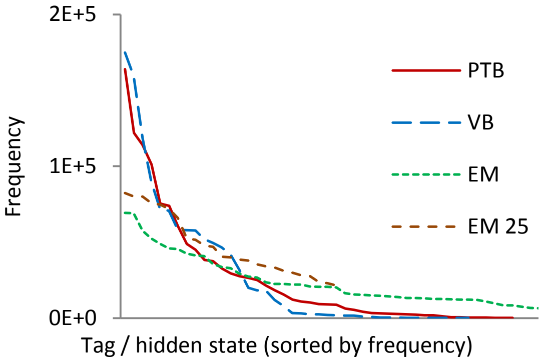

Figure 3: The average number of words labeled with each hidden state or tag for the EM, VB (with $\alpha_x = \alpha_y = 0.1$) and EM-25 estimators (EM-25 is the EM estimator with 25 hidden states).

ruoka for pointing this out). Since we evaluated the accuracy of the estimated tags after each iteration, it was important that decoding be done efficiently as well. While most researchers use Viterbi decoding to find the most likely state sequence, maximum marginal decoding (which labels the observation x_i with the state y_i that maximizes the marginal probability $\mathrm{P}(y_i|\mathbf{x}, \theta, \phi)$) is faster because it re-uses the forward and backward tables already constructed by the Forward-Backward algorithm. Moreover, in separate experiments we found that the maximum marginal state sequence almost always scored higher than the Viterbi state sequence in all of our evaluations, and at modest numbers of iterations (up to 50) often scored more than 5% better.

We also noticed a wide variance in the performance of models due to random initialization (both θ and ϕ are initially jittered to break symmetry); this wide variance was observed with all of the estimators investigated in this paper. This means we cannot compare estimators on the basis of single runs, so we ran each estimator 10 times from different random starting points and report both mean and standard deviation for all scores.

Finally, we also experimented with annealing, in which the parameters θ and ϕ are raised to the power $1/T$, where T is a "temperature" parameter that is slowly lowered toward 1 at each iteration according to some "annealing schedule". We experimented with a variety of starting temperatures and annealing schedules (e.g., linear, exponential, etc), but were unable to find any that produced models whose likelihoods were significantly higher (i.e., the models fit better) than those found without annealing.

The evaluation of the models produced by the EM and other estimators is presented in Table 1. It is difficult to compare these with previous work, but Haghighi and Klein (2006) report that in a completely unsupervised setting, their MRF model, which uses a large set of additional features and a more complex estimation procedure, achieves an average 1-to-1 accuracy of 41.3%. Because they provide no information about the variance in this accuracy it is difficult to tell whether there is a significant difference between their estimator and the EM estimator, but it is clear that when EM is run long enough, the performance of even very simple models like the bitag HMM is better than generally recognized.

As Table 1 makes clear, the EM estimator produces models that are extremely competitive in many-to-1 accuracy and Variation of Information, but are significantly worse in 1-to-1 accuracy. We can understand these results by comparing the distribution of words to hidden states to the distribution of words to POS tags in the gold-standard evaluation corpus. As Figure 3 shows, the distribution of words to POS tags is highly skewed, with just 6 POS tags, NN, IN, NNP, DT, JJ and NNS, accounting for over 55% of the tokens in the corpus. By contrast, the EM distribution is much flatter. This also explains why the many-to-1 accuracy is so much better than the one-to-one accuracy; presumably several hidden

Table 1: Evaluation of models produced by the various estimators. The values of the Dirichlet prior parameters for α_x and α_y appear in the estimator name for the VB and GS estimators, and the number of hidden states is given in parentheses. Reported values are means over all runs, followed by standard deviations. 10 runs were performed for each of the EM and VB estimators, while 5 runs were performed for the GS estimators. Each EM and VB run consisted of 1,000 iterations, while each GS run consisted of 50,000 iterations. For the estimators with 10 runs, a 3-standard error 95% confidence interval is approximately the same as the standard deviation.

states are being mapped onto a single POS tag. This is also consistent with the fact that the cross-entropy $H(T|Y)$ of tags given hidden states is relatively low (i.e., given a hidden state, the tag is relatively predictable), while the cross-entropy $H(Y|T)$ is relatively high.

4 Bayesian estimation via Gibbs Sampling and Variational Bayes

A Bayesian estimator combines a likelihood term $\mathrm{P}(\mathbf{x}|\theta, \phi)$ and a prior $\mathrm{P}(\theta, \phi)$ to estimate the posterior probability of a model or hidden state sequence. We can use a Bayesian prior to bias our estimator towards models that generate more skewed distributions. Because HMMs (and PCFGs) are products of multinomials, Dirichlet distributions are a particularly natural choice for the priors since they are conjugate to multinomials, which simplifies both the mathematical and computational aspects of the problem. The precise form of the model we investigated is:

$$\begin{array}{lcll}
\theta_y & | & \alpha_y & \sim & \mathrm{Dir}(\alpha_y) \\
\phi_y & | & \alpha_x & \sim & \mathrm{Dir}(\alpha_x) \\
y_i & | & y_{i-1} = y & \sim & \mathrm{Multi}(\theta_y) \\
x_i & | & y_i = y & \sim & \mathrm{Multi}(\phi_y)
\end{array}$$

Informally, α_y controls the sparsity of the state-to-state transition probabilities while α_x controls the sparsity of the state-to-observation emission probabilities. As α_x approaches zero the prior strongly prefers models in which each hidden state emits as few words as possible. This captures the intuition that most word types only belong to one POS, since the minimum number of non-zero state-to-observation transitions occurs when each observation type is emitted from only one state. Similarly, as α_y approaches zero the state-to-state transitions become sparser.

There are two main techniques for Bayesian estimation of such models: Markov Chain Monte Carlo (MCMC) and Variational Bayes (VB). MCMC encompasses a broad range of sampling techniques, including component-wise Gibbs sampling, which is the MCMC technique we used here (Robert and Casella, 2004; Bishop, 2006). In general, MCMC techniques do not produce a single model that characterizes the posterior, but instead produce a stream of samples from the posterior. The application of MCMC techniques, including Gibbs sampling, to HMM inference problems is relatively well-known: see Besag (2004) for a tutorial introduction and Goldwater and Griffiths (2007) for an application of Gibbs sampling to HMM inference for semi-supervised and unsupervised POS tagging.

The Gibbs sampler produces state sequences $\mathbf{y}$ sampled from the posterior distribution:

$$\mathrm{P}(\mathbf{y}|\mathbf{x},\alpha) \propto \int \mathrm{P}(\mathbf{x},\mathbf{y}|\theta,\phi)\mathrm{P}(\theta|\alpha_y)\mathrm{P}(\phi|\alpha_x)\, d\theta\, d\phi$$

Because Dirichlet priors are conjugate to multinomials, it is possible to integrate out the model parameters θ and ϕ to yield the conditional distribution for y_i shown in Figure 4. For each observation x_i in turn, we resample its state y_i conditioned on the states $\mathbf{y}_{-i}$ of the other observations; eventually the distribution of state sequences converges to the desired posterior.

Each iteration of the Gibbs sampler is much faster than the Forward-Backward algorithm (both take time linear in the length of the string, but for an HMM with s hidden states, each iteration of the Gibbs sampler takes $O(s)$ time while each iteration of the Forward-Backward algorithm takes $O(s^2)$ time), so we ran 50,000 iterations of all samplers (which takes roughly the same elapsed time as 1,000 Forward-Backward iterations).

As can be seen from Table 1, the posterior state sequences we obtained are not particularly good. Further, when we examined how the posterior likelihoods varied with increasing iterations of Gibbs sampling, it became apparent that the likelihood was still increasing after 50,000 iterations. Moreover, when comparing posterior likelihoods from different runs with the same prior parameters but different random number seeds, none of the likelihoods crossed, which one would expect if the samplers had converged and were mixing well (Robert and Casella, 2004). Just as with EM, we experimented with a variety of annealing regimes, but were unable to find any which significantly improved accuracy or posterior likelihood.

We also experimented with evaluating state sequences found using maximum posterior decoding (i.e., model parameters are estimated from the posterior sample, and used to perform maximum posterior decoding) rather than the samples from the posterior produced by the Gibbs sampler. We found that the maximum posterior decoding sequences usually scored higher than the posterior samples, but the scores converged after the first thousand iterations. Since the posterior samples are produced as a by-product of Gibbs sampling while maximum posterior decoding requires an additional time consuming step that does not have much impact on scores, we used the posterior samples to produce the results in Table 1.

In contrast to MCMC, Variational Bayesian inference attempts to find the function $Q(\mathbf{y},\theta,\phi)$ that minimizes an upper bound of the negative log likelihood (Jordan et al., 1999):

$$\begin{aligned} & -\log \mathrm{P}(\mathbf{x}) \\ = \ & -\log \int Q(\mathbf{y},\theta,\phi)\frac{\mathrm{P}(\mathbf{x},\mathbf{y},\theta,\phi)}{Q(\mathbf{y},\theta,\phi)}\, d\mathbf{y}\, d\theta\, d\phi \\ \leq & -\int Q(\mathbf{y},\theta,\phi)\log\frac{\mathrm{P}(\mathbf{x},\mathbf{y},\theta,\phi)}{Q(\mathbf{y},\theta,\phi)}\, d\mathbf{y}\, d\theta\, d\phi \quad (3) \end{aligned}$$

The upper bound in (3) is called the *Variational Free Energy*. We make a "mean-field" assumption that the posterior can be well approximated by a factorized model Q in which the state sequence $\mathbf{y}$ does not covary with the model parameters θ, ϕ (this will be true if, for example, there is sufficient data that the posterior distribution has a peaked mode):

$$\mathrm{P}(\mathbf{x},\mathbf{y},\theta,\phi) \ \approx \ Q(\mathbf{y},\theta,\phi) \ = \ Q_1(\mathbf{y})Q_2(\theta,\phi)$$

The calculus of variations is used to minimize the KL divergence between the desired posterior distribution and the factorized approximation. It turns out that if the likelihood and conjugate prior belong to exponential families then the optimal Q_1 and Q_2 do too, and there is an EM-like iterative procedure that finds locally-optimal model parameters (Bishop, 2006).

This procedure is especially attractive for HMM inference, since it involves only a minor modification to the M-step of the Forward-Backward algorithm. MacKay (1997) and Beal (2003) describe Variational Bayesian (VB) inference for HMMs in detail, and Kurihara and Sato (2006) describe VB for PCFGs (which only involves a minor modification to the M-step of the Inside-Outside algorithm). Specifically, the E-step for VB inference for HMMs is the same as in EM, while the M-step is as follows:

$$\begin{aligned} \tilde{\theta}^{(\ell+1)}_{y'|y} &= f(\mathrm{E}[n_{y',y}] + \alpha_y)/f(\mathrm{E}[n_y] + s\alpha_y) \quad (4) \\ \tilde{\phi}^{(\ell+1)}_{x|y} &= f(\mathrm{E}[n_{x,y}] + \alpha_x)/f(\mathrm{E}[n_y] + m\alpha_x) \\ f(v) &= \exp(\psi(v)) \\ \psi(v) &= (v > 7) \ ? \ g(v - \tfrac{1}{2}) : (\psi(v+1) - 1)/v \\ g(x) &\approx \log(x) + 0.04167x^{-2} + 0.00729x^{-4} \\ & \quad +0.00384x^{-6} - 0.00413x^{-8} \ldots \quad (5) \end{aligned}$$

$$\mathrm{P}(y_i|\mathbf{x},\mathbf{y}_{-i},\alpha) \quad \propto \quad \left(\frac{n_{x_i,y_i}+\alpha_x}{n_{y_i}+m\alpha_x}\right)\left(\frac{n_{y_i,y_{i-1}}+\alpha_y}{n_{y_{i-1}}+s\alpha_y}\right)\left(\frac{n_{y_{i+1},y_i}+\mathrm{I}(y_{i-1}=y_i=y_{i+1})+\alpha_y}{n_{y_i}+\mathrm{I}(y_{i-1}=y_i)}\right)$$

Figure 4: The conditional distribution for state y_i used in the Gibbs sampler, which conditions on the states $\mathbf{y}_{-i}$ for all observations *except* x_i. Here m is the number of possible observations (i.e., the size of the vocabulary), s is the number of hidden states and $\mathrm{I}(\cdot)$ is the indicator function (i.e., equal to one if its argument is true and zero otherwise), $n_{x,y}$ is the number of times observation x occurs with state y, $n_{y',y}$ is the number of times state y' follows y, and n_y is the number of times state y occurs; these counts are from $(\mathbf{x}_{-i},\mathbf{y}_{-i})$, i.e., excluding x_i and y_i.

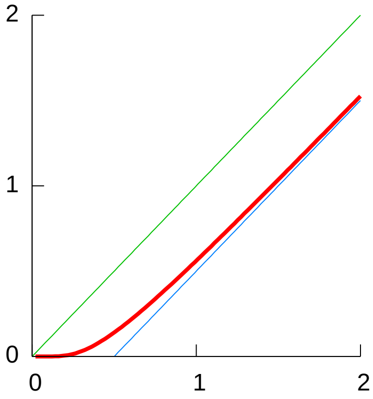

Figure 5: The scaling function $y = f(x) = \exp\psi(x)$ (curved line), which is bounded above by the line $y = x$ and below by the line $y = x - 0.5$.

where ψ is the *digamma function* (the derivative of the log gamma function; (5) gives an asymptotic approximation), and the remaining quantities are just as in the EM updates (2), i.e., $n_{x,y}$ is the number of times observation x occurs with state y, $n_{y',y}$ is the number of times state y' follows y, n_y is the number of occurences of state y, s is the number of hidden states and m is the number of observations; all expectations are taken with respect to the variational parameters $(\tilde{\theta}^{(\ell)}, \tilde{\phi}^{(\ell)})$.

A comparison between (4) and (2) reveals two differences between the EM and VB updates. First, the Dirichlet prior parameters α are added to the expected counts. Second, these posterior counts (which are in fact parameters of the Dirichlet posterior Q_2) are passed through the function $f(v) = \exp\psi(v)$, which is plotted in Figure 5. When $v \gg 0$, $f(v) \approx v - 0.5$, so roughly speaking, VB for multinomials involves adding $\alpha - 0.5$ to the expected counts when they are much larger than zero, where α is the Dirichlet prior parameter. Thus VB can be viewed as a more principled version of the well-known ad hoc technique for approximating Bayesian estimation with EM that involves adding $\alpha - 1$ to the expected counts. However, in the ad hoc approach the expected count plus $\alpha - 1$ may be less than zero, resulting in a value of zero for the corresponding parameter (Johnson et al., 2007; Goldwater and Griffiths, 2007). VB avoids this problem because $f(v)$ is always positive when $v > 0$, even when v is small. Note that because the counts are passed through f, the updated values for $\tilde{\theta}$ and $\tilde{\phi}$ in (4) are in general *not* normalized; this is because the variational free energy is only an upper bound on the negative log likelihood (Beal, 2003).

We found that in general VB performed much better than GS. Computationally it is very similar to EM, and each iteration takes essentially the same time as an EM iteration. Again, we experimented with annealing in the hope of speeding convergence, but could not find an annealing schedule that significantly lowered the variational free energy (the quantity that VB optimizes). While we had hoped that the Bayesian prior would bias VB toward a common solution, we found the same sensitivity to initial conditions as we found with EM, so just as for EM, we ran the estimator for 1,000 iterations with 10 different random initializations for each combination of prior parameters. Table 1 presents the results of VB runs with several different values for the Dirichlet prior parameters. Interestingly, we obtained our best performance on 1-to-1 accuracy when the Dirchlet prior $\alpha_x = 0.1$, a relatively large number, but best performance on many-to-1 accuracy was achieved with a much lower value for the Dirichlet prior, namely $\alpha_x = 10^{-4}$. The Dirichlet prior α_y that controls sparsity of the state-to-state transitions had little effect on the results. We did not have computational resources to fully explore other values for the prior (a set of 10 runs for one set of parameter values takes 25 computer days).

As Figure 3 shows, VB can produce distributions of hidden states that are peaked in the same way that POS tags are. In fact, with the priors used here, VB produces state sequences in which only a subset of the possible HMM states are in fact assigned to observations. This shows that rather than fixing the number of hidden states in advance, the Bayesian prior can determine the number of states; this idea is more fully developed in the *infinite HMM* of Beal et al. (2002) and Teh et al. (2006).

5 Reducing the number of hidden states

EM already performs well in terms of the many-to-1 accuracy, but we wondered if there might be some way to improve its 1-to-1 accuracy and VI score. In section 3 we suggested that one reason for its poor performance in these evaluations is that the distributions of hidden states it finds tend to be fairly flat, compared to the empirical distribution of POS tags. As section 4 showed, a suitable Bayesian prior can bias the estimator towards more peaked distributions, but we wondered if there might be a simpler way of achieving the same result.

We experimented with dramatic reductions in the number of hidden states in the HMMs estimated by EM. This should force the hidden states to be more densely populated and improve 1-to-1 accuracy, even though this means that there will be no hidden states that can possibly map onto the less frequent POS tags (i.e., we will get these words wrong). In effect, we abandon the low-frequency POS tags in the hope of improving the 1-to-1 accuracy of the high-frequency tags.

As Table 1 shows, this markedly improves both the 1-to-1 accuracy and the VI score. A 25-state HMM estimated by EM performs effectively as well as the best VB model in terms of both 1-to-1 accuracy and VI score, and runs 4 times faster because it has only half the number of hidden states.

6 Conclusion and future work

This paper studied why EM seems to do so badly in HMM estimation for unsupervised POS tagging. In fact, we found that it doesn't do so badly at all: the bitag HMM estimated by EM achieves a mean 1-to-1 tagging accuracy of 40%, which is approximately the same as the 41.3% reported by (Haghighi and Klein, 2006) for their sophisticated MRF model.

Then we noted the distribution of words to hidden states found by EM is relatively uniform, compared to the distribution of words to POS tags in the evaluation corpus. This provides an explanation of why the many-to-1 accuracy of EM is so high while the 1-to-1 accuracy and VI of EM is comparatively low. We showed that either by using a suitable Bayesian prior or by simply reducing the number of hidden states it is possible to significantly improve both the 1-to-1 accuracy and the VI score, achieving a 1-to-1 tagging accuracy of 46%.

We also showed that EM and other estimators take much longer to converge than usually thought, and often require several hundred iterations to achieve optimal performance. We also found that there is considerable variance in the performance of all of these estimators, so in general multiple runs from different random starting points are necessary in order to evaluate an estimator's performance.

Finally, there may be more sophisticated ways of improving the 1-to-1 accuracy and VI score than the relatively crude methods used here that primarily reduce the number of available states. For example, we might obtain better performance by using EM to infer an HMM with a large number of states, and then using some kind of distributional clustering to group similar HMM states; these clusters, rather than the underlying states, would be interpreted as the POS tag labels. Also, the Bayesian framework permits a wide variety of different priors besides Dirichlet priors explored here. For example, it should be possible to encode linguistic knowledge such markedness preferences in a prior, and there are other linguistically uninformative priors, such the "entropic priors" of Brand (1999), that may be worth exploring.

Abstract

This paper describes a probabilistic model for coordination disambiguation integrated into syntactic and case structure analysis. Our model probabilistically assesses the parallelism of a candidate coordinate structure using syntactic/semantic similarities and cooccurrence statistics. We integrate these probabilities into the framework of fully-lexicalized parsing based on large-scale case frames. This approach simultaneously addresses two tasks of coordination disambiguation: the detection of coordinate conjunctions and the scope disambiguation of coordinate structures. Experimental results on web sentences indicate the effectiveness of our approach.

1 Introduction

Coordinate structures are a potential source of syntactic ambiguity in natural language. Since their interpretation directly affects the meaning of the text, their disambiguation is important for natural language understanding.

Coordination disambiguation consists of the following two tasks:

- the detection of coordinate conjunctions,
- and finding the scope of coordinate structures.

In English, for example, coordinate structures are triggered by coordinate conjunctions, such as *and* and *or*. In a coordinate structure that consists of more than two conjuncts, commas, which have various usages, also function like coordinate conjunctions. Recognizing true coordinate conjunctions from such possible coordinate conjunctions is a task of coordination disambiguation (Kurohashi, 1995). The other is the task of identifying the range of coordinate phrases or clauses.

Previous work on coordination disambiguation has focused on the task of addressing the scope ambiguity (e.g., (Agarwal and Boggess, 1992; Goldberg, 1999; Resnik, 1999; Chantree et al., 2005)). Kurohashi and Nagao proposed a similarity-based method to resolve both of the two tasks for Japanese (Kurohashi and Nagao, 1994). Their method, however, heuristically detects coordinate conjunctions by considering only similarities between possible conjuncts, and thus cannot disambiguate the following cases[1]:

(1) a. *kanojo-to gakkou-ni itta*
she-cmi school-acc went

(ϕ went to school with her)

b. *kanojo-to watashi-ga goukaku-shita*
she-cnj I-nom passed an exam

(she and I passed an exam)

In sentence (1a), postposition "*to*" is used as a comitative case marker, but in sentence (1b), postposition "*to*" is used as a coordinate conjunction.

To resolve this ambiguity, predicative case frames are required. Case frames describe what kinds of

[1] In this paper, we use the following abbreviations: nom (nominative), acc (accusative), abl (ablative), cmi (comitative), cnj (conjunction) and TM (topic marker).

Proceedings of the 2007 Joint Conference on Empirical Methods in Natural Language Processing and Computational Natural Language Learning, pp. 306–314, Prague, June 2007.

Table 1: Case frame examples (Examples are written in English. Numbers following each example represent its frequency.).

	CS	Examples
yaku (1) (broil)	*ga*	I:18, person:15, craftsman:10, · · ·
	wo	bread:2484, meat:1521, cake:1283, · · ·
	de	oven:1630, frying pan:1311, · · ·
yaku (2) (have difficulty)	*ga*	teacher:3, government:3, person:3, · · ·
	wo	fingers:2950
	ni	attack:18, action:15, son:15, · · ·
yaku (3) (burn)	*ga*	maker:1, distributor:1

	wo	tooth:5959, molar:27, foretooth:12
	de	brush:38, salt:13, powder:12, · · ·
⋮	⋮	⋮

nouns are related to each predicate. For example, a case frame of "*iku*" (go) has a "*to*" case slot filled with the examples such as "*kanojo*" (she) or human. On the other hand, "*goukaku-suru*" (pass an exam) does not have a "*to*" case slot but does have a "*ga*" case slot filled with "*kanojo*" (she) and "*watashi*" (I). These case frames provide the information for disambiguating the postpositions "*to*" in sentences (1a) and (1b): (1a) is not coordinate and (1b) is coordinate.

This paper proposes a method for integrating coordination disambiguation into probabilistic syntactic and case structure analysis. This method simultaneously addresses the two tasks of coordination disambiguation by utilizing syntactic/semantic parallelism in possible coordinate structures and lexical preferences in large-scale case frames. We use the case frames that were automatically constructed from the web (Table 1). In addition, cooccurrence statistics of coordinate conjuncts are incorporated into this model.

2 Related Work

Previous work on coordination disambiguation has focused mainly on finding the scope of coordinate structures.

Agarwal and Boggess proposed a method for identifying coordinate conjuncts (Agarwal and Boggess, 1992). Their method simply matches parts of speech and hand-crafted semantic tags of the head words of the coordinate conjuncts. They tested their method using the Merck Veterinary Manual and found their method had an accuracy of 81.6%.

Resnik described a similarity-based approach for coordination disambiguation of nominal compounds (Resnik, 1999). He proposed a similarity measure based on the notion of shared information content. He conducted several experiments using the Penn Treebank and reported an F-measure of approximately 70%.

Goldberg applied a cooccurrence-based probabilistic model to determine the attachments of ambiguous coordinate phrases with the form "n1 p n2 cc n3" (Goldberg, 1999). She collected approximately 120K unambiguous pairs of two coordinate words from a raw newspaper corpus for a one-year period and estimated parameters from these statistics. Her method achieved an accuracy of 72% using the Penn Treebank.

Chantree et al. presented a binary classifier for coordination ambiguity (Chantree et al., 2005). Their model is based on word distribution information obtained from the British National Corpus. They achieved an F-measure ($\beta = 0.25$) of 47.4% using their own test set.

The previously described methods focused on coordination disambiguation. Some research has been undertaken that integrated coordination disambiguation into parsing.

Kurohashi and Nagao proposed a Japanese parsing method that included coordinate structure detection (Kurohashi and Nagao, 1994). Their method first detects coordinate structures in a sentence, and then heuristically determines the dependency structure of the sentence under the constraints of the detected coordinate structures. Their method correctly analyzed 97 Japanese sentences out of 150.

Charniak and Johnson used some features of syntactic parallelism in coordinate structures for their MaxEnt reranking parser (Charniak and Johnson, 2005). The reranker achieved an F-measure of 91.0%, which is higher than that of their generative parser (89.7%). However, they used a numerous number of features, and the contribution of the

parallelism features is unknown.

Dubey et al. proposed an unlexicalized PCFG parser that modified PCFG probabilities to condition the existence of syntactic parallelism (Dubey et al., 2006). They obtained an F-measure increase of 0.4% over their baseline parser (73.0%). Experiments with a lexicalized parser were not conducted in their work.

A number of machine learning-based approaches to Japanese parsing have been developed. Among them, the best parsers are the SVM-based dependency analyzers (Kudo and Matsumoto, 2002; Sassano, 2004). In particular, Sassano added some features to improve his parser by enabling it to detect coordinate structures (Sassano, 2004). However, the added features did not contribute to improving the parsing accuracy. This failure can be attributed to the inability to consider global parallelism.

3 Coordination Ambiguity in Japanese

In Japanese, the *bunsetsu* is a basic unit of dependency that consists of one or more content words and the following zero or more function words. A bunsetsu corresponds to a base phrase in English and "*eojeol*" in Korean.

Coordinate structures in Japanese are classified into three types. The first type is the *coordinate noun phrase*.

(2) *nagai enpitsu-**to** keshigomu-wo katta*
long pencil-cnj eraser-acc bought

(bought a long pencil and an eraser)

We can find these phrases by referring to the words listed in Table 2-a.

The second type is the *coordinate predicative clause*, in which two or more predicates form a coordinate structure.

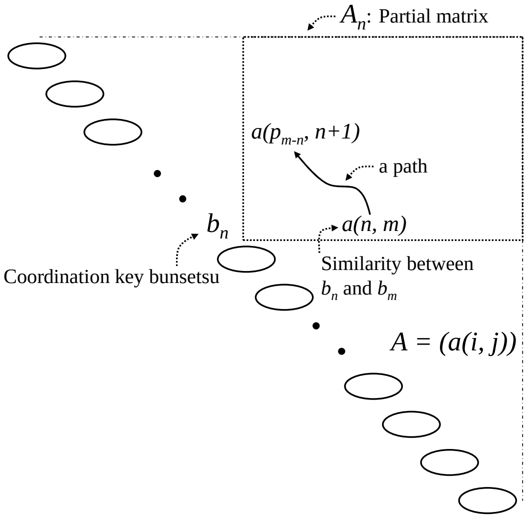

Figure 1: Method using triangular matrix.

(3) *kanojo-to kekkon-**shi** ie-wo katta*
she-cmi married house-acc bought

(married her and bought a house)

We can find these clauses by referring to the words and ending forms listed in Table 2-b.

The third type is the *incomplete coordinate structure*, in which some parts of coordinate predicative clauses are present.

(4) *Tom-wa inu-**wo,** Jim-wa neko-**wo** kau*
Tom-TM dog-acc Jim-TM cat-acc buys

(Tom (buys) a dog, and Jim buys a cat)

We can find these structures by referring to the words listed in Table 2-c and also the correspondence of case-marking postpositions.

For all of these types, we can detect the possibility of a coordinate structure by looking for a *coordination key bunsetsu* that accompanies one of the words listed in Table 2 (in total, we have 52 coordination expressions). That is to say, the left and right sides of a coordination key bunsetsu constitute possible pre- and post-conjuncts, and the key bunsetsu is located at the end of the pre-conjunct. The size of the conjuncts corresponds to the scope of the coordination.

4 Calculating Similarity between Possible Coordinate Conjuncts

We assess the parallelism of potential coordinate structures in a probabilistic parsing model. In this

Figure 2: Example of calculating path scores.

section, we describe a method for calculating similarities between potential coordinate conjuncts.

To measure the similarity between potential pre- and post-conjuncts, a lot of work on the coordination disambiguation used the similarity between conjoined heads. However, not only the conjoined heads but also other components in conjuncts have some similarity and furthermore structural parallelism. Therefore, we use a method to calculate the similarity between two whole coordinate conjuncts (Kurohashi and Nagao, 1994). The remainder of this section contains a brief description of this method.

To calculate similarity between two series of bunsetsus, a triangular matrix, A, is used (illustrated in Figure 1).

$$A = (a(i,j)) \ \ (0 \leq i \leq l; i \leq j \leq l) \qquad (1)$$

where l is the number of bunsetsus in a sentence, diagonal element $a(i,j)$ is the i-th bunsetsu, and element $a(i,j) \ \ (i < j)$ is the similarity value between bunsetsus b_i and b_j. A similarity value between two bunsetsus is calculated on the basis of POS matching, exact word matching, and their semantic closeness in a thesaurus tree (Kurohashi and Nagao, 1994). We use the *Bunruigoihyo* thesaurus, which contains 96,000 Japanese words (The National Institute for Japanese Language, 2004).

To detect a coordinate structure involving a key bunsetsu, b_n, we consider only a partial matrix (denoted A_n), that is, the upper right part of b_n (Figure 1).

$$A_n = (a(i,j)) \ \ (0 \leq i \leq n; n+1 \leq j \leq l) \qquad (2)$$

To specify correspondences between bunsetsus in potential pre- and post-conjuncts, a path is defined as follows:

$$path ::= (a(p_1, m), \quad a(p_2, m-1), \ \ldots, \\ a(p_{m-n}, n+1)) \qquad (3)$$

where $n+1 \leq m \leq l$, $a(p_1, m) \neq 0$, $p_1 = n$, $p_i \geq p_{i+1}$, $(1 \leq i \leq m-n-1)$.
That is, a path represents a series of elements from a non-zero element in the lowest row in A_n to an element in the leftmost column in A_n. The path has an only element in each column and extends toward the upper left. The series of bunsetsus on the left side of the path and the series under the path are potential conjuncts for key b_n. Figure 2 shows an example of a path.

A path score is defined based on the following criteria:

- the sum of each element's points on the path
- penalty points when the path extends non-diagonally (which causes conjuncts of unbalanced lengths)
- bonus points on expressions signaling the beginning or ending of a coordinate structure, such as "*kaku*" (each) and *nado*" (and so on)
- the total score of the above criteria is divided by the square root of the number of bunsetsus covered by the path for normalization

The score of each path is calculated using a dynamic programming method. We consider each path as a candidate of pre- and post-conjuncts.

5 Integrated Probabilistic Model for Syntactic, Coordinate and Case Structure Analysis

This section describes a method of integrating coordination disambiguation into a probabilistic parsing model. The integrated model is based on a fully-lexicalized probabilistic model for Japanese syntactic and case structure analysis (Kawahara and Kurohashi, 2006b).

5.1 Outline of the Model

This model gives a probability to each possible dependency structure, T, and case structure, L, of the input sentence, S, and outputs the syntactic, coordinate and case structure that have the highest probability. That is to say, the model selects the syntactic structure, T_{best}, and the case structure, L_{best}, that maximize the probability, $P(T, L|S)$:

$$\begin{aligned}(T_{best}, L_{best}) &= \text{argmax}_{(T,L)} P(T, L|S)\\ &= \text{argmax}_{(T,L)} \frac{P(T, L, S)}{P(S)}\\ &= \text{argmax}_{(T,L)} P(T, L, S) \qquad (4)\end{aligned}$$

The last equation is derived because $P(S)$ is constant.

The model considers a clause as a generation unit and generates the input sentence from the end of the sentence in turn. The probability $P(T, L, S)$ is defined as the product of probabilities for generating clause C_i as follows:

$$P(T, L, S) = \prod_{i=1..n} P(C_i, rel_{ih_i}|C_{h_i}) \qquad (5)$$

where n is the number of clauses in S, C_{h_i} is C_i's modifying clause, and rel_{ih_i} is the dependency relation between C_i and C_{h_i}. The main clause, C_n, at the end of a sentence does not have a modifying head, but a virtual clause C_{h_n} = EOS (End Of Sentence) is inserted. Dependency relation rel_{ih_i} is first classified into two types C (coordinate) and D (normal dependency), and C is further divided into five classes according to the binned similarity (path score) of conjuncts. Therefore, rel_{ih_i} can be one of the following six classes.

$$rel_{ih_i} = \{D, C0, C1, C2, C3, C4\} \qquad (6)$$

For instance, $C0$ represents a coordinate relation with a similarity of less than 1, and $C4$ represents a coordinate relation with a similarity of 4 or more.

$P(tabe-te, C0 \mid bentou-wa\ kaet-ta)$

Figure 3: Example of probability calculation.

For example, consider the sentence shown in Figure 3. There are four possible dependency structures in this figure, and the product of the probabilities for each structure indicated below the tree is calculated. Finally, the model chooses the structure with the highest probability (in this case T_1 is chosen).

Clause C_i is decomposed into its clause type, f_i, (including the predicate's inflection and function words) and its remaining content part $C_i{}'$. Clause C_{h_i} is also decomposed into its content part, $C_{h_i}{}'$, and its clause type, f_{h_i}.

$$\begin{aligned}&P(C_i, rel_{ih_i}|C_{h_i}) = P(C_i{}', f_i, rel_{ih_i}|C_{h_i}{}', f_{h_i})\\ &= P(C_i{}', rel_{ih_i}|f_i, C_{h_i}{}', f_{h_i}) \times P(f_i|C_{h_i}{}', f_{h_i})\\ &\approx P(C_i{}', rel_{ih_i}|f_i, C_{h_i}{}') \times P(f_i|f_{h_i}) \qquad (7)\end{aligned}$$

Equation (7) is derived because the content part, $C_i{}'$, is usually independent of its modifying head type, f_{h_i}, and in most cases, the type, f_i, is independent of the content part of its modifying head, C_{h_i}.

We call $P(C_i{}', rel_{ih_i}|f_i, C_{h_i}{}')$ *generative probability of a case and coordinate structure*, and $P(f_i|f_{h_i})$ *generative probability of a clause type*. The latter is the probability of generating function words including topic markers and punctuation marks, and is estimated using a syntactically annotated corpus in the same way as (Kawahara and Kurohashi, 2006b).

The generative probability of a case and coordinate structure can be rewritten as follows:

$$\begin{aligned}&P(C_i{}', rel_{ih_i}|f_i, C_{h_i}{}')\\ &= P(C_i{}'|rel_{ih_i}, f_i, C_{h_i}{}') \times P(rel_{ih_i}|f_i, C_{h_i}{}')\\ &\approx P(C_i{}'|rel_{ih_i}, f_i, C_{h_i}{}') \times P(rel_{ih_i}|f_i) \qquad (8)\end{aligned}$$

Equation (8) is derived because dependency relations (coordinate or not) heavily depend on modifier's types including coordination keys. We call $P(C_i{}'|rel_{ih_i}, f_i, C_{h_i}{}')$ *generative probability of a case structure*, and $P(rel_{ih_i}|f_i)$ *generative probability of a coordinate structure*. The following two subsections describe these probabilities.

5.2 Generative Probability of Coordinate Structure

The most important feature to decide whether two clauses are coordinate is coordination keys. Therefore, we consider a coordination key, k_i, as clause type f_i. The generative probability of a coordinate structure, $P(rel_{ih_i}|f_i)$, is defined as follows:

$$P(rel_{ih_i}|f_i) = P(rel_{ih_i}|k_i) \tag{9}$$

We classified coordination keys into 52 classes according to the classification proposed by (Kurohashi and Nagao, 1994). If type f_i does not contain a coordination key, the relation is always D (normal dependency), that is $P(rel_{ih_i}|f_i) = P(D|\phi) = 1$.

The generative probability of a coordinate structure was estimated from a syntactically annotated corpus using maximum likelihood. We used the Kyoto Text Corpus (Kurohashi and Nagao, 1998), which consists of 40K Japanese newspaper sentences.

5.3 Generative Probability of Case Structure

We consider that a case structure consists of a predicate, v_i, a case frame, CF_l, and a case assignment, CA_k. Case assignment CA_k represents correspondences between the input case components and the case slots shown in Figure 4. Thus, the generative probability of a case structure is decomposed as follows:

$$\begin{aligned}
&P(C_i{}'|rel_{ih_i}, f_i, C_{h_i}{}') \\
&= P(v_i, CF_l, CA_k|rel_{ih_i}, f_i, C_{h_i}{}') \\
&= P(v_i|rel_{ih_i}, f_i, C_{h_i}{}') \\
&\quad \times P(CF_l|rel_{ih_i}, f_i, C_{h_i}{}', v_i) \\
&\quad \times P(CA_k|rel_{ih_i}, f_i, C_{h_i}{}', v_i, CF_l) \\
&\approx P(v_i|rel_{ih_i}, f_i, w_{h_i}) \\
&\quad \times P(CF_l|v_i) \\
&\quad \times P(CA_k|CF_l, f_i)
\end{aligned} \tag{10}$$

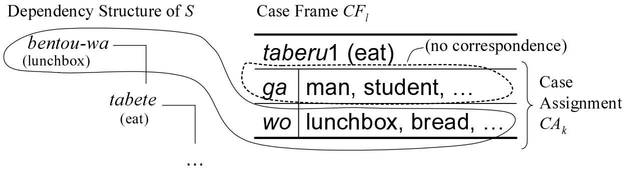

Figure 4: Example of case assignment.

The above approximation is given because it is natural to consider that the predicate v_i depends on its modifying head w_{h_i} instead of the whole modifying clause, that the case frame CF_l only depends on the predicate v_i, and that the case assignment CA_k depends on the case frame CF_l and the clause type f_i.

The generative probabilities of case frames and case assignments are estimated from case frames themselves in the same way as (Kawahara and Kurohashi, 2006b). The remainder of this section describes the generative probability of a predicate, $P(v_i|rel_{ih_i}, f_i, w_{h_i})$.

The generative probability of a predicate captures cooccurrences of coordinate or non-coordinate phrases. This kind of information is not handled in case frames, which aggregate only predicate-argument relations.

The generative probability of a predicate mainly depends on a coordination key in the clause type, f_i, as well as the generative probability of a coordinate structure. We define this probability as follows:

$$P(v_i|rel_{ih_i}, f_i, w_{h_i}) = P(v_i|rel_{ih_i}, k_i, w_{h_i})$$

If $C_i{}'$ is a nominal clause and consists of a noun n_i, we consider the following probability in stead of equation (10):

$$P_n(C_i{}'|rel_{ih_i}, f_i, C_{h_i}{}') \approx P(n_i|rel_{ih_i}, f_i, w_{h_i})$$

This is because a noun does not have a case frame and any case components in the current framework.

To estimate these probabilities, we first applied a conventional parsing system with coordination disambiguation to a huge corpus, and collected coordinate bunsetsus from the parses. We used KNP[2] (Kurohashi and Nagao, 1994) as the parser and a web corpus consisting of 470M Japanese sentences (Kawahara and Kurohashi, 2006a). The generative probability of a predicate was estimated from the

[2] http://nlp.kuee.kyoto-u.ac.jp/nl-resource/knp-e.html

collected coordinate bunsetsus using maximum likelihood.

5.4 Practical Issue

The proposed model considers all the possible dependency structures including coordination ambiguities. To reduce this high computational cost, we introduced the CKY framework to the search.

Each parameter in the model is smoothed by using several back-off levels in the same way as (Collins, 1999). Smoothing parameters are optimized using a development corpus.

6 Experiments

We evaluated the coordinate structures and dependency structures that were outputted by our model. The case frames used in this paper were automatically constructed from 470M Japanese sentences obtained from the web. Some examples of the case frames are listed in Table 1 (Kawahara and Kurohashi, 2006a).

In this work, the parameters related to unlexical types are calculated from a small tagged corpus of newspaper articles, and lexical parameters are obtained from a huge web corpus. To evaluate the effectiveness of our fully-lexicalized model, our experiments are conducted using web sentences. As the test corpus, we prepared 759 web sentences [3]. The web sentences were manually annotated using the same criteria as the Kyoto Text Corpus. We also used the Kyoto Text Corpus as a development corpus to optimize the smoothing parameters. The system input was automatically tagged using the JUMAN morphological analyzer [4].

We used two baseline systems for comparative purposes: the rule-based dependency parser, KNP (Kurohashi and Nagao, 1994), and the probabilistic model of syntactic and case structure analysis (Kawahara and Kurohashi, 2006b), in which coordination disambiguation is the same as that of KNP.

6.1 Evaluation of Detection of Coordinate Structures

First, we evaluated detecting coordinate structures, namely whether a coordination key bunsetsu triggers a coordinate structure. Table 3 lists the experimental results. The F-measure of our method is slightly higher than that of the baseline method (KNP). In particular, our method achieved good precision.

Table 3: Experimental results of detection of coordinate structures.

	baseline	proposed
precision	366/460 (79.6%)	361/435 (83.0%)
recall	366/447 (81.9%)	361/447 (80.8%)
F-measure	– (80.7%)	– (81.9%)

6.2 Evaluation of Dependency Parsing

Secondly, we evaluated the dependency structures analyzed by the proposed model. Evaluating the scope ambiguity of coordinate structures is subsumed within this dependency evaluation. The dependency structures obtained were evaluated with regard to dependency accuracy — the proportion of correct dependencies out of all dependencies except for the last dependency in the sentence end [5]. Table 4 lists the dependency accuracy. In this table, “syn” represents the rule-based dependency parser, KNP, “syn+case” represents the probabilistic parser of syntactic and case structure (Kawahara and Kurohashi, 2006b), and “syn+case+coord” represents our proposed model. The proposed model significantly outperformed both of the baseline systems (McNemar’s test; $p < 0.01$).

In the table, the dependency accuracies are classified into four types on the basis of the bunsetsu classes (PB: predicate bunsetsu and NB: noun bunsetsu) of a dependent and its head. “syn+case” outperformed “syn”. In particular, the accuracy of predicate-argument relations (“NB→PB”) was improved, but the accuracies of “NB→NB” and “PB→PB” decreased. “syn+case+coord” outperformed the two baselines for all of the types. Not only the accuracy of predicate-argument relations (“NB→PB”) but also the accuracies of coordinate noun/predicate bunsetsus (related to “NB→NB” and “PB→PB”) were improved. These improvements are conduced by the integration of coordination disambiguation and syntactic/case structure analysis.

[3] The test set was not used to construct case frames and estimate probabilities.

[4] http://nlp.kuee.kyoto-u.ac.jp/nl-resource/juman-e.html

[5] Since Japanese is head-final, the second last bunsetsu unambiguously depends on the last bunsetsu, and the last bunsetsu has no dependency.

Table 4: Experimental results of dependency parsing.

	syn	syn+case	syn+case+coord
all	3,833/4,436 (86.4%)	3,852/4,436 (86.8%)	3,893/4,436 (87.8%)
NB→PB	1,637/1,926 (85.0%)	1,664/1,926 (86.4%)	1,684/1,926 (87.4%)
NB→NB	1,032/1,136 (90.8%)	1,029/1,136 (90.6%)	1,037/1,136 (91.3%)
PB→PB	654/817 (80.0%)	647/817 (79.2%)	659/817 (80.7%)
PB→NB	510/557 (91.6%)	512/557 (91.9%)	513/557 (92.1%)

To compare our results with a state-of-the-art discriminative dependency parser, we input the same test corpus into an SVM-based Japanese dependency parser, CaboCha[6](Kudo and Matsumoto, 2002). Its dependency accuracy was 86.3% (3,829/4,436), which is equivalent to that of "syn" (KNP). This low accuracy is attributed to the out-of-domain training corpus. That is, the parser is trained on a newspaper corpus, whereas the test corpus is obtained from the web, because of the non-availability of a tagged web corpus that is large enough to train a supervised parser.

6.3 Discussion

Figure 5 shows some analysis results, where the dotted lines represent the analysis by the baseline, "syn+case", and the solid lines represent the analysis by the proposed method, "syn+case+coord". These sentences are incorrectly analyzed by the baseline but correctly analyzed by the proposed method. For instance, in sentence (1), the noun phrase coordination of "*apurikeesyon*" (application) and "*doraiba*" (driver) can be correctly analyzed. This is because the case frame of "*insutooru-sareru*" (installed) is likely to generate "*doraiba*", and "*apurikeesyon*" and "*doraiba*" are likely to be coordinated.

One of the causes of errors in dependency parsing is the mismatch between analysis results and annotation criteria. As per the annotation criteria, each bunsetsu has only one modifying head. Therefore, in some cases, even if analysis results are semantically correct, they are judged as incorrect from the viewpoint of the annotation. For example, in sentence (4) in Figure 6, the baseline method, "syn", correctly recognized the head of "*iin-wa*" (commissioner-TM) as "*hirakimasu*" (open). However, the proposed method incorrectly judged it as "*oujite-imasuga*" (offer). Both analysis results can be considered to be semantically correct, but from the viewpoint of our annotation criteria, the latter is not a syntactic relation (i.e., incorrect), but an ellipsis relation. This kind of error is caused by the strong lexical preference considered in our method.

To address this problem, it is necessary to simultaneously evaluate not only syntactic relations but also indirect relations, such as ellipses and anaphora. This kind of mismatch also occurred for the detection of coordinate structures.

Another errors were caused by an inherent characteristic of generative models. Generative models have some advantages, such as their application to language models. However, it is difficult to incorporate various features that seem to be useful for addressing syntactic and coordinate ambiguity. We plan to apply discriminative reranking to the n-best parses produced by our generative model in the same way as (Charniak and Johnson, 2005).

7 Conclusion

This paper has described an integrated probabilistic model for coordination disambiguation and syntactic/case structure analysis. This model takes advantage of lexical preference of a huge raw corpus and large-scale case frames and performs coordination disambiguation and syntactic/case analysis simultaneously. The experiments indicated the effectiveness of our model. Our future work involves incorporating ellipsis resolution to develop an integrated model for syntactic, case, and ellipsis analysis.

A New Perceptron Algorithm for Sequence Labeling with Non-local Features

Jun'ichi Kazama and Kentaro Torisawa
Japan Advanced Institute of Science and Technology (JAIST)
Asahidai 1-1, Nomi, Ishikawa, 923-1292 Japan
{kazama, torisawa}@jaist.ac.jp

Abstract

We cannot use non-local features with current major methods of sequence labeling such as CRFs due to concerns about complexity. We propose a new perceptron algorithm that can use non-local features. Our algorithm allows the use of all types of non-local features whose values are determined from the sequence and the labels. The weights of local and non-local features are learned together in the training process with guaranteed convergence. We present experimental results from the CoNLL 2003 named entity recognition (NER) task to demonstrate the performance of the proposed algorithm.

1 Introduction

Many NLP tasks such as POS tagging and named entity recognition have recently been solved as sequence labeling. Discriminative methods such as Conditional Random Fields (CRFs) (Lafferty et al., 2001), Semi-Markov Random Fields (Sarawagi and Cohen, 2004), and perceptrons (Collins, 2002a) have been popular approaches for sequence labeling because of their excellent performance, which is mainly due to their ability to incorporate many kinds of overlapping and non-independent features.

However, the common limitation of these methods is that the features are limited to "local" features, which only depend on a very small number of labels (usually two: the previous and the current). Although this limitation makes training and inference tractable, it also excludes the use of possibly useful "non-local" features that are accessible after all labels are determined. For example, non-local features such as "same phrases in a document do not have different entity classes" were shown to be useful in named entity recognition (Sutton and McCallum, 2004; Bunescu and Mooney, 2004; Finkel et al., 2005; Krishnan and Manning, 2006).

We propose a new perceptron algorithm in this paper that can use non-local features along with local features. Although several methods have already been proposed to incorporate non-local features (Sutton and McCallum, 2004; Bunescu and Mooney, 2004; Finkel et al., 2005; Roth and Yih, 2005; Krishnan and Manning, 2006; Nakagawa and Matsumoto, 2006), these present a problem that the types of non-local features are somewhat constrained. For example, Finkel et al. (2005) enabled the use of non-local features by using Gibbs sampling. However, it is unclear how to apply their method of determining the parameters of a non-local model to other types of non-local features, which they did not used. Roth and Yih (2005) enabled the use of hard constraints on labels by using integer linear programming. However, this is equivalent to only allowing non-local features whose weights are fixed to negative infinity. Krishnan and Manning (2006) divided the model into two CRFs, where the second model uses the output of the first as a kind of non-local information. However, it is not possible to use non-local features that depend on the labels of the very candidate to be scored. Nakagawa and Matsumoto (2006) used a Bolzmann distribution to model the correlation of the POS of words having the same lexical form in a document. However, their method can only be applied when there are convenient links such as the same lexical form.

Since non-local features have not yet been extensively investigated, it is possible for us to find new useful non-local features. Therefore, our objective in this study was to establish a framework, where all

Proceedings of the 2007 Joint Conference on Empirical Methods in Natural Language Processing and Computational Natural Language Learning, pp. 315–324, Prague, June 2007. ©2007 Association for Computational Linguistics

types of non-local features are allowed.

With non-local features, we cannot use efficient procedures such as forward-backward procedures and the Viterbi algorithm that are required in training CRFs (Lafferty et al., 2001) and perceptrons (Collins, 2002a). Recently, several methods (Collins and Roark, 2004; Daumé III and Marcu, 2005; McDonald and Pereira, 2006) have been proposed with similar motivation to ours. These methods alleviate this problem by using some approximation in perceptron-type learning.

In this paper, we follow this line of research and try to solve the problem by extending Collins' perceptron algorithm (Collins, 2002a). We exploited the not-so-familiar fact that we can design a perceptron algorithm with guaranteed convergence if we can find at least one wrong labeling candidate even if we cannot perform exact inference. We first ran the A* search only using local features to generate n-best candidates (this can be efficiently performed), and then we only calculated the true score with non-local features for these candidates to find a wrong labeling candidate. The second key idea was to update the weights of local features during training if this was necessary to generate sufficiently good candidates. The proposed algorithm combined these ideas to achieve guaranteed convergence and effective learning with non-local features.

The remainder of the paper is organized as follows. Section 2 introduces the Collins' perceptron algorithm. Although this algorithm is the starting point for our algorithm, its baseline performance is not outstanding. Therefore, we present a margin extension to the Collins' perceptron in Section 3. This margin perceptron became the direct basis of our algorithm. We then explain our algorithm for non-local features in Section 4. We report the experimental results using the CoNLL 2003 shared task dataset in Section 6.

2 Perceptron Algorithm for Sequence Labeling

Collins (2002a) proposed an extension of the perceptron algorithm (Rosenblatt, 1958) to sequence labeling. Our aim in sequence labeling is to assign label $y_i \in \mathcal{Y}$ to each word $x_i \in \mathcal{X}$ in a sequence. We denote sequence $x_1, \ldots, x_T$ as $\boldsymbol{x}$ and the corresponding labels as $\boldsymbol{y}$. We assume weight vector $\boldsymbol{\alpha} \in R^d$ and feature mapping Φ that maps each $(\boldsymbol{x}, \boldsymbol{y})$ to feature vector $\Phi(\boldsymbol{x}, \boldsymbol{y}) = (\Phi_1(\boldsymbol{x}, \boldsymbol{y}), \cdots, \Phi_d(\boldsymbol{x}, \boldsymbol{y})) \in R^d$. The model determines the labels by:

$$\boldsymbol{y}' = \mathrm{argmax}_{\boldsymbol{y} \in \mathcal{Y}^{|\boldsymbol{x}|}} \Phi(\boldsymbol{x}, \boldsymbol{y}) \cdot \boldsymbol{\alpha},$$

where $\cdot$ denotes the inner product. The aim of the learning algorithm is to obtain an appropriate weight vector, $\boldsymbol{\alpha}$, given training set $\{(\boldsymbol{x}_1, \boldsymbol{y}_1^*), \cdots, (\boldsymbol{x}_L, \boldsymbol{y}_L^*)\}$.

The learning algorithm, which is illustrated in Collins (2002a), proceeds as follows. The weight vector is initialized to zero. The algorithm passes over the training examples, and each sequence is decoded using the current weights. If $\boldsymbol{y}'$ is not the correct answer $\boldsymbol{y}^*$, the weights are updated according to the following rule.

$$\boldsymbol{\alpha}_{new} = \boldsymbol{\alpha} + \Phi(\boldsymbol{x}, \boldsymbol{y}^*) - \Phi(\boldsymbol{x}, \boldsymbol{y}').$$

This algorithm is proved to converge (i.e., there are no more updates) in the separable case (Collins, 2002a).[1] That is, if there exist weight vector $\boldsymbol{U}$ (with $||\boldsymbol{U}|| = 1$), δ (> 0), and R (> 0) that satisfy:

$$\begin{array}{ll} \forall i, \forall \boldsymbol{y} \in \mathcal{Y}^{|\boldsymbol{x}_i|} & \Phi(\boldsymbol{x_i}, \boldsymbol{y_i}^*) \cdot \boldsymbol{U} - \Phi(\boldsymbol{x_i}, \boldsymbol{y}) \cdot \boldsymbol{U} \geq \delta, \\ \forall i, \forall \boldsymbol{y} \in \mathcal{Y}^{|\boldsymbol{x}_i|} & ||\Phi(\boldsymbol{x_i}, \boldsymbol{y_i}^*) - \Phi(\boldsymbol{x_i}, \boldsymbol{y})|| \leq R, \end{array}$$

the number of updates is at most R^2/δ^2.

The perceptron algorithm only requires one candidate $\boldsymbol{y}'$ for each sequence $\boldsymbol{x_i}$, unlike the training of CRFs where all possible candidates need to be considered. This inherent property is the key to training with non-local features. However, note that the tractability of learning and inference relies on how efficiently $\boldsymbol{y}'$ can be found. In practice, we can find $\boldsymbol{y}'$ efficiently using a Viterbi-type algorithm only when the features are all local, i.e., $\Phi_s(\boldsymbol{x}, \boldsymbol{y})$ can be written as the sum of (two label) local features ϕ_s as $\Phi_s(\boldsymbol{x}, \boldsymbol{y}) = \sum_i^T \phi_s(\boldsymbol{x}, y_{i-1}, y_i)$. This locality constraint is also required to make the training of CRFs tractable (Lafferty et al., 2001).

One problem with the perceptron algorithm described so far is that it offers no treatment for overfitting. Thus, Collins (2002a) also proposed an averaged perceptron, where the final weight vector is

[1] Collins (2002a) also provided proof that guaranteed "good" learning for the non-separable case. However, we have only considered the separable case throughout the paper.

Algorithm 3.1: Perceptron with margin for sequence labeling (parameters: C)

```
$\boldsymbol{\alpha} \leftarrow \mathbf{0}$
until no more updates do
  for $i \leftarrow 1$ to $L$ do
    $\boldsymbol{y}' = \text{argmax}_{\boldsymbol{y}} \Phi(\boldsymbol{x}_i, \boldsymbol{y}) \cdot \boldsymbol{\alpha}$
    $\boldsymbol{y}'' = \text{2nd-best}_{\boldsymbol{y}} \Phi(\boldsymbol{x}_i, \boldsymbol{y}) \cdot \boldsymbol{\alpha}$
    if $\boldsymbol{y}' \neq \boldsymbol{y}_i^*$ then
      $\boldsymbol{\alpha} = \boldsymbol{\alpha} + \Phi(\boldsymbol{x}_i, \boldsymbol{y}_i^*) - \Phi(\boldsymbol{x}_i, \boldsymbol{y}')$
    else if $\Phi(\boldsymbol{x}_i, \boldsymbol{y}_i^*) \cdot \boldsymbol{\alpha} - \Phi(\boldsymbol{x}_i, \boldsymbol{y}'') \cdot \boldsymbol{\alpha} \leq C$ then
      $\boldsymbol{\alpha} = \boldsymbol{\alpha} + \Phi(\boldsymbol{x}_i, \boldsymbol{y}_i^*) - \Phi(\boldsymbol{x}_i, \boldsymbol{y}'')$
```

the average of all weight vectors during training. Howerver, we found in our experiments that the averaged perceptron performed poorly in our setting. We therefore tried to make the perceptron algorithm more robust to overfitting. We will describe our extension to the perceptron algorithm in the next section.

3 Margin Perceptron Algorithm for Sequence Labeling

We extended a perceptron with a margin (Krauth and Mézard, 1987) to sequence labeling in this study, as Collins (2002a) extended the perceptron algorithm to sequence labeling.

In the case of sequence labeling, the margin is defined as:

$$\gamma(\boldsymbol{\alpha}) = \min_{\boldsymbol{x}_i} \min_{\boldsymbol{y} \neq \boldsymbol{y}_i^*} \frac{\Phi(\boldsymbol{x_i}, \boldsymbol{y_i}^*) \cdot \boldsymbol{\alpha} - \Phi(\boldsymbol{x_i}, \boldsymbol{y}) \cdot \boldsymbol{\alpha}}{||\boldsymbol{\alpha}||}$$

Assuming that the best candidate, $\boldsymbol{y}'$, equals the correct answer, $\boldsymbol{y}^*$, the margin can be re-written as:

$$= \min_{\boldsymbol{x}_i} \frac{\Phi(\boldsymbol{x_i}, \boldsymbol{y_i}^*) \cdot \boldsymbol{\alpha} - \Phi(\boldsymbol{x_i}, \boldsymbol{y''}) \cdot \boldsymbol{\alpha}}{||\boldsymbol{\alpha}||},$$

where $\boldsymbol{y}'' = \text{2nd-best}_{\boldsymbol{y}} \Phi(\boldsymbol{x}_i, \boldsymbol{y}) \cdot \boldsymbol{\alpha}$. Using this relation, the resulting algorithm becomes Algorithm 3.1. The algorithm tries to enlarge the margin as much as possible, as well as make the best scoring candidate equal the correct answer.

Constant C in Algorithm 3.1 is a tunable parameter, which controls the trade-off between the margin and convergence time. Based on the proofs in Collins (2002a) and Li et al. (2002), we can prove that the algorithm converges within $(2C + R^2)/\delta^2$ updates and that $\gamma(\boldsymbol{\alpha}) \geq \delta C/(2C + R^2) = (\delta/2)(1 - (R^2/(2C + R^2)))$ after training. As can be seen, the margin approaches at least half of true margin δ (at the cost of infinite training time), as $C \rightarrow \infty$.

Note that if the features are all local, the second-best candidate (generally n-best candidates) can also be found efficiently by using an A* search that uses the best scores calculated during a Viterbi search as the heuristic estimation (Soong and Huang, 1991).

There are other methods for improving robustness by making margin larger for the structural output problem. Such methods include ALMA (Gentile, 2001) used in (Daumé III and Marcu, 2005)[2], MIRA (Crammer et al., 2006) used in (McDonald et al., 2005), and Max-Margin Markov Networks (Taskar et al., 2003). However, to the best of our knowledge, there has been no prior work that has applied a perceptron with a margin (Krauth and Mézard, 1987) to structured output.[3] Our method described in this section is one of the easiest to implement, while guaranteeing a large margin. We found in the experiments that our method outperformed the Collins' averaged perceptron by a large margin.

4 Algorithm

4.1 Definition and Basic Idea

Having described the basic perceptron algorithms, we will know explain our algorithm that learns the weights of local and non-local features in a unified way.

Assume that we have local features and non-local features. We use the superscript, l, for local features as $\Phi_i^l(\boldsymbol{x}, \boldsymbol{y})$ and g for non-local features as $\Phi_i^g(\boldsymbol{x}, \boldsymbol{y})$. Then, feature mapping is written as $\Phi^a(\boldsymbol{x}, \boldsymbol{y}) = \Phi^l(\boldsymbol{x}, \boldsymbol{y}) + \Phi^g(\boldsymbol{x}, \boldsymbol{y}) = (\Phi_1^l(\boldsymbol{x}, \boldsymbol{y}), \cdots, \Phi_n^l(\boldsymbol{x}, \boldsymbol{y}), \Phi_{n+1}^g(\boldsymbol{x}, \boldsymbol{y}), \cdots, \Phi_d^g(\boldsymbol{x}, \boldsymbol{y}))$. Here, we define:

$$\begin{aligned} \Phi^l(\boldsymbol{x}, \boldsymbol{y}) &= (\Phi_1^l(\boldsymbol{x}, \boldsymbol{y}), \cdots, \Phi_n^l(\boldsymbol{x}, \boldsymbol{y}), 0, \cdots, 0) \\ \Phi^g(\boldsymbol{x}, \boldsymbol{y}) &= (0, \cdots, 0, \Phi_{n+1}^g(\boldsymbol{x}, \boldsymbol{y}), \cdots, \Phi_d^g(\boldsymbol{x}, \boldsymbol{y})) \end{aligned}$$

Ideally, we want to determine the labels using the whole feature set as:

$$\boldsymbol{y}' = \text{argmax}_{\boldsymbol{y} \in \mathcal{Y}^{|\boldsymbol{x}|}} \Phi^a(\boldsymbol{x}, \boldsymbol{y}) \cdot \boldsymbol{\alpha}.$$

[2] (Daumé III and Marcu, 2005) also presents the method using the averaged perceptron (Collins, 2002a)

[3] For re-ranking problems, Shen and Joshi (2004) proposed a perceptron algorithm that also uses margins. The difference is that our algorithm trains the sequence labeler itself and is much simpler because it only aims at labeling.

Algorithm 4.1: Candidate algorithm (parameters: n, C)

```
$\boldsymbol{\alpha} \leftarrow \mathbf{0}$
until no more updates do
  for $i \leftarrow 1$ to $L$ do
    $\{\boldsymbol{y}^n\} = \text{n-best}_{\boldsymbol{y}} \Phi^l(\boldsymbol{x}_i, \boldsymbol{y}) \cdot \boldsymbol{\alpha}$
    $\boldsymbol{y}' = \text{argmax}_{\boldsymbol{y} \in \{\boldsymbol{y}^n\}} \Phi^a(\boldsymbol{x}_i, \boldsymbol{y}) \cdot \boldsymbol{\alpha}$
    $\boldsymbol{y}'' = \text{2nd-best}_{\boldsymbol{y} \in \{\boldsymbol{y}^n\}} \Phi^a(\boldsymbol{x}_i, \boldsymbol{y}) \cdot \boldsymbol{\alpha}$
    if $\boldsymbol{y}' \neq \boldsymbol{y_i}^*$
        & $\Phi^a(\boldsymbol{x}_i, \boldsymbol{y}_i^*) \cdot \boldsymbol{\alpha} - \Phi^a(\boldsymbol{x}_i, \boldsymbol{y}') \cdot \boldsymbol{\alpha} \leq C$ then
      $\boldsymbol{\alpha} = \boldsymbol{\alpha} + \Phi^a(\boldsymbol{x}_i, \boldsymbol{y}_i^*) - \Phi^a(\boldsymbol{x}_i, \boldsymbol{y}')$
    else if $\Phi^a(\boldsymbol{x}_i, \boldsymbol{y}_i^*) \cdot \boldsymbol{\alpha} - \Phi^a(\boldsymbol{x}_i, \boldsymbol{y}'') \cdot \boldsymbol{\alpha} \leq C$ then
      $\boldsymbol{\alpha} = \boldsymbol{\alpha} + \Phi^a(\boldsymbol{x}_i, \boldsymbol{y}_i^*) - \Phi^a(\boldsymbol{x}_i, \boldsymbol{y}'')$
```

Algorithm 4.2: Perceptron with local and non-local features (parameters: n, C^a, C^l)

```
$\boldsymbol{\alpha} \leftarrow \mathbf{0}$
until no more updates do
  for $i \leftarrow 1$ to $L$ do
    $\{\boldsymbol{y}^n\} = \text{n-best}_{\boldsymbol{y}} \Phi^l(\boldsymbol{x}_i, \boldsymbol{y}) \cdot \boldsymbol{\alpha}$
    $\boldsymbol{y}' = \text{argmax}_{\boldsymbol{y} \in \{\boldsymbol{y}^n\}} \Phi^a(\boldsymbol{x}_i, \boldsymbol{y}) \cdot \boldsymbol{\alpha}$
    $\boldsymbol{y}'' = \text{2nd-best}_{\boldsymbol{y} \in \{\boldsymbol{y}^n\}} \Phi^a(\boldsymbol{x}_i, \boldsymbol{y}) \cdot \boldsymbol{\alpha}$
    if $\boldsymbol{y}' \neq \boldsymbol{y}_i^*$
        & $\Phi^a(\boldsymbol{x}_i, \boldsymbol{y}_i^*) \cdot \boldsymbol{\alpha} - \Phi^a(\boldsymbol{x}_i, \boldsymbol{y}') \cdot \boldsymbol{\alpha} \leq C^a$ then
      $\boldsymbol{\alpha} = \boldsymbol{\alpha} + \Phi^a(\boldsymbol{x}_i, \boldsymbol{y}_i^*) - \Phi^a(\boldsymbol{x}_i, \boldsymbol{y}')$                    (A)
    else if $\Phi^a(\boldsymbol{x}_i, \boldsymbol{y}_i^*) \cdot \boldsymbol{\alpha} - \Phi^a(\boldsymbol{x}_i, \boldsymbol{y}'') \cdot \boldsymbol{\alpha} \leq C^a$ then
      $\boldsymbol{\alpha} = \boldsymbol{\alpha} + \Phi^a(\boldsymbol{x}_i, \boldsymbol{y}_i^*) - \Phi^a(\boldsymbol{x}_i, \boldsymbol{y}'')$                    (A)
    else
      (B)  if $\boldsymbol{y}^1 \neq \boldsymbol{y_i}^*$ then ($\boldsymbol{y}^1$ represents the best in $\{\boldsymbol{y}^n\}$)
             $\boldsymbol{\alpha} = \boldsymbol{\alpha} + \Phi^l(\boldsymbol{x}_i, \boldsymbol{y}_i^*) - \Phi^l(\boldsymbol{x}_i, \boldsymbol{y}^1)$
           else if $\Phi^l(\boldsymbol{x}_i, \boldsymbol{y}_i^*) \cdot \boldsymbol{\alpha} - \Phi^l(\boldsymbol{x}_i, \boldsymbol{y}^2) \cdot \boldsymbol{\alpha} \leq C^l$ then
             $\boldsymbol{\alpha} = \boldsymbol{\alpha} + \Phi^l(\boldsymbol{x}_i, \boldsymbol{y}_i^*) - \Phi^l(\boldsymbol{x}_i, \boldsymbol{y}^2)$
```

However, if there are non-local features, it is impossible to find the highest scoring candidate efficiently, since we cannot use the Viterbi algorithm. Thus, we cannot use the perceptron algorithms described in the previous sections. The training of CRFs is also intractable for the same reason.

To deal with this problem, we first relaxed our objective. The modified objective was to find a good model from those with the form:

$$\begin{aligned} \{\boldsymbol{y}^n\} &= \text{n-best}_{\boldsymbol{y}} \Phi^l(\boldsymbol{x}, \boldsymbol{y}) \cdot \boldsymbol{\alpha} \\ \boldsymbol{y}' &= \text{argmax}_{\boldsymbol{y} \in \{\boldsymbol{y}^n\}} \Phi^a(\boldsymbol{x}, \boldsymbol{y}) \cdot \boldsymbol{\alpha}, \quad (1) \end{aligned}$$

That is, we first generate n-best candidates $\{\boldsymbol{y}^n\}$ under the local model, $\Phi^l(\boldsymbol{x}, \boldsymbol{y}) \cdot \boldsymbol{\alpha}$. This can be done efficiently using the A* algorithm. We then find the best scoring candidate under the total model, $\Phi^a(\boldsymbol{x}, \boldsymbol{y}) \cdot \boldsymbol{\alpha}$, only from these n-best candidates. If n is moderately small, this can also be done in a practical amount of time.

This resembles the re-ranking approach (Collins and Duffy, 2002; Collins, 2002b). However, unlike the re-ranking approach, the local model, $\Phi^l(\boldsymbol{x}, \boldsymbol{y}) \cdot \boldsymbol{\alpha}$, and the total model, $\Phi^a(\boldsymbol{x}, \boldsymbol{y}) \cdot \boldsymbol{\alpha}$, correlate since they share a part of the vector and are trained at the same time in our algorithm. The re-ranking approach has the disadvantage that it is necessary to use different training corpora for the first model and for the second, or to use cross validation type training, to make the training for the second meaningful. This reduces the effective size of training data or increases training time substantially. On the other hand, our algorithm has no such disadvantage.

However, we are no longer able to find the highest scoring candidate under $\Phi^a(\boldsymbol{x}, \boldsymbol{y}) \cdot \boldsymbol{\alpha}$ exactly with this approach. We cannot thus use the perceptron algorithms directly. However, by examining the proofs in Collins (2002a), we can see that the essential condition for convergence is that the weights are always updated using some $\boldsymbol{y}$ ($\neq \boldsymbol{y}^*$) that satisfies:

$$\Phi(\boldsymbol{x}_i, \boldsymbol{y}_i^*) \cdot \boldsymbol{\alpha} - \Phi(\boldsymbol{x}_i, \boldsymbol{y}) \cdot \boldsymbol{\alpha} \leq 0$$

($\leq C$ in the case of a perceptron with a margin). (2)

That is, $\boldsymbol{y}$ does not necessarily need to be the exact best candidate or the exact second-best candidate. The algorithm also converges in a finite number of iterations even with Eq. (1) as long as Eq. (2) is satisfied.

4.2 Candidate Algorithm

The algorithm we came up with first based on the above idea, is Algorithm 4.1. We first find the n-best candidates using the local model, $\Phi^l(\boldsymbol{x}, \boldsymbol{y}) \cdot \boldsymbol{\alpha}$. At this point, we can determine the value of the non-local features, $\Phi^g(\boldsymbol{x}, \boldsymbol{y})$, to form the whole feature vector, $\Phi^a(\boldsymbol{x}, \boldsymbol{y})$, for the n-best candidates. Next, we re-score and sort them using the total model, $\Phi^a(\boldsymbol{x}, \boldsymbol{y}) \cdot \boldsymbol{\alpha}$, to find a candidate that violates the margin condition. We call this algorithm the "candidate algorithm". After the training has finished, $\Phi^a(\boldsymbol{x}_i, \boldsymbol{y}_i^*) \cdot \boldsymbol{\alpha} - \Phi^a(\boldsymbol{x}_i, \boldsymbol{y}) \cdot \boldsymbol{\alpha} > C$ is guaranteed for all $(\boldsymbol{x}_i, \boldsymbol{y})$ where $\boldsymbol{y} \in \{\boldsymbol{y}^n\}, \boldsymbol{y} \neq \boldsymbol{y}^*$. At first glance, this seems sufficient condition for good models. However, this is not true because if $\boldsymbol{y}^* \notin \{\boldsymbol{y}^n\}$, the inference defined by Eq. (1) is not guaranteed to find the correct answer, $\boldsymbol{y}^*$. In fact, this algorithm does not work well with non-local features as we found in the experiments.

4.3 Final Algorithm

Our idea for improving the above algorithm is that the local model, $\Phi^l(\boldsymbol{x}, \boldsymbol{y}) \cdot \boldsymbol{\alpha}$, must at least be so good that $\boldsymbol{y}^* \in \{\boldsymbol{y}^n\}$. To achieve this, we added a modification term that was intended to improve the local model when the local model was not good enough even when the total model was good enough.

The final algorithm resulted in Algorithm 4.2. As can be seen, the part marked (B) has been added. We call this algorithm the "proposed algorithm". Note that the algorithm prioritizes the update of the total model, (A), over that of the local model, (B), although the opposite is also possible. Also note that the update of the local model in (B) is "aggressive" since it updates the weights until the best candidate output by the local model becomes the correct answer and satisfies the margin condition. A "conservative" updating, where we cease the update when the n-best candidates contain the correct answer, is also possible from our idea above. We made these choices since they worked better than the other alternatives.

The tunable parameters are the local margin parameter, C^l, the total margin parameter, C^a, and n for the n-best search. We used $C = C^l = C^a$ in this study to reduce the search space.

We can prove that the algorithm in Algorithm 4.2 also converges in a finite number of iterations. It converges within $(2C + R^2)/\delta^2$ updates, assuming that there exist weight vector $\boldsymbol{U}^l$ (with $||\boldsymbol{U}^l|| = 1$ and $U_i^l = 0 \ \ (n+1 \leq i \leq d)$), δ (> 0), and R (> 0) that satisfy:

$$\forall i, \forall \boldsymbol{y} \in \mathcal{Y}^{|\boldsymbol{x}_i|} \ \ \Phi^l(\boldsymbol{x_i}, \boldsymbol{y_i}^*) \cdot \boldsymbol{U}^l - \Phi^l(\boldsymbol{x_i}, \boldsymbol{y}) \cdot \boldsymbol{U}^l \geq \delta,$$

$$\forall i, \forall \boldsymbol{y} \in \mathcal{Y}^{|\boldsymbol{x}_i|} \ \ ||\Phi^a(\boldsymbol{x_i}, \boldsymbol{y_i}^*) - \Phi^a(\boldsymbol{x_i}, \boldsymbol{y})|| \leq R.$$

In addition, we can prove that $\gamma'(\boldsymbol{\alpha}) \geq \delta C/(2C + R^2)$ for the margin after convergence, where $\gamma'(\boldsymbol{\alpha})$ is defined as:

$$\min_{\boldsymbol{x}_i} \min_{\boldsymbol{y} \in \{\boldsymbol{y}^n\}, \neq \boldsymbol{y}_i^*} \frac{\Phi^a(\boldsymbol{x_i}, \boldsymbol{y_i}^*) \cdot \boldsymbol{\alpha} - \Phi^a(\boldsymbol{x_i}, \boldsymbol{y}) \cdot \boldsymbol{\alpha}}{||\boldsymbol{\alpha}||}$$

See Appendix A for the proofs.

We also incorporated the idea behind Bayes point machines (BPMs) (Herbrich and Graepel, 2000) to improve the robustness of our method further. BPMs try to cancel out overfitting caused by the order of examples, by training several models by shuffling the training examples.[4] However, it is very time consuming to run the complete training process several times. We thus ran the training in only one pass over the shuffled examples several times, and used the averaged output weight vectors as a new initial weight vector, because we thought that the early part of training would be more seriously affected by the order of examples. We call this "BPM initialization". [5]

5 Named Entity Recognition and Non-Local Features

We evaluated the performance of the proposed algorithm using the named entity recognition task. We adopted IOB (IOB2) labeling (Ramshaw and Marcus, 1995), where the first word of an entity of class "C" is labeled "B-C", the words in the entity are labeled "I-C", and other words are labeled "O".

We used non-local features based on Finkel et al. (2005). These features are based on observations such as "same phrases in a document tend to have the same entity class" (phrase consistency) and "a sub-phrase of a phrase tends to have the same entity class as the phrase" (sub-phrase consistency). We also implemented the "majority" version of these features as used in Krishnan and Manning (2006). In addition, we used non-local features, which are based on the observation that "entities tend to have the same entity class if they are in the same conjunctive or disjunctive expression" as in "$\cdots$ in U.S., EU, and Japan" (conjunction consistency). This type of non-local feature was not used by Finkel et al. (2005) or Krishnan and Manning (2006).

6 Experiments

6.1 Data and Setting

We used the English dataset of the CoNLL 2003 named entity shared task (Tjong et al., 2003) for the experiments. It is a corpus of English newspaper articles, where four entity classes, PER, LOC, ORG, and MISC are annotated. It consists of training, development, and testing sets (14,987, 3,466,

[4] The results for the perceptron algorithms generally depend on the order of the training examples.

[5] Note that we can prove that the perceptron algorithms converge even though the weight vector is not initialized as $\boldsymbol{\alpha} = \boldsymbol{0}$.

and 3,684 sentences, respectively). Automatically assigned POS tags and chunk tags are also provided. The CoNLL 2003 dataset contains document boundary markers. We concatenated the sentences in the same document according to these markers.[6] This generated 964 documents for the training set, 216 documents for the development set, and 231 documents for the testing set. The documents generated as above become the sequence, $\boldsymbol{x}$, in the learning algorithms.

We first evaluated the baseline performance of a CRF model, the Collins' perceptron, and the Collins' averaged perceptron, as well as the margin perceptron, with only local features. We next evaluated the performance of our perceptron algorithm proposed for non-local features.

We used the local features summarized in Table 1, which are similar to those used in other studies on named entity recognition. We omitted features whose surface part listed in Table 1 occurred less than twice in the training corpus.

We used CRF++ (ver. 0.44)[7] as the basis of our implementation. We implemented scaling, which is similar to that for HMMs (see such as (Rabiner, 1989)), in the forward-backward phase of CRF training to deal with very long sequences due to sentence concatenation.[8]

We used Gaussian regularization (Chen and Rosenfeld, 2000) for CRF training to avoid overfitting. The parameter of the Gaussian, σ^2, was tuned using the development set. We also tuned the margin parameter, C, for the margin perceptron algorithm.[9] The convergence of CRF training was determined by checking the log-likelihood of the model. The convergence of perceptron algorithms was determined by checking the per-word labeling error, since the number of updates was not zero even after a large number of iterations in practice. We stopped training when the relative change in these values became less than a pre-defined threshold (0.0001) for at least three iterations.

Table 1: Local features used. The value of a node feature is determined from the current label, y_0, and a surface feature determined only from $\boldsymbol{x}$. The value of an edge feature is determined by the previous label, y_{-1}, the current label, y_0, and a surface feature. Used surface features are the word (w), the downcased word (wl), the POS tag (pos), the chunk tag (chk), the prefix of the word of length n (pn), the suffix (sn), the word form features: 2d - cp (these are based on (Bikel et al., 1999)), and the gazetteer features: go for ORG, gp for PER, and gm for MISC. These represent the (longest) match with an entry in the gazetteer by using IOB2 tags.

Node features: $\{\text{""}, \mathrm{x}_{-2}, \mathrm{x}_{-1}, \mathrm{x}_{0}, \mathrm{x}_{+1}, \mathrm{x}_{+2}\} \times y_0$
x =, w, wl, pos, chk, p1, p2, p3, p4, s1, s2, s3, s4, 2d, 4d, d&a, d&-, d&/, d&,, d&., n, ic, ac, l, cp, go, gp, gm
Edge features: $\{\text{""}, \mathrm{x}_{-2}, \mathrm{x}_{-1}, \mathrm{x}_{0}, \mathrm{x}_{+1}, \mathrm{x}_{+2}\} \times y_{-1} \times y_0$

We used $n = 20$ (n of the n-best) for training since we could not use too a large n because it would have slowed down training. However, we could examine a larger n during testing, since the testing time did not dominate the time for the experiment. We found an interesting property for n in our preliminary experiment. We found that an even larger n in testing (written as n') achieved higher accuracy, although it is natural to assume that the same n that was used in training would also be appropriate for testing. We thus used $n' = 100$ to evaluate performance during parameter tuning. After finding the best C with $n' = 100$, we varied n' to investigate its

[6] We used sentence concatenation even when only using local features, since we found it does not degrade accuracy (rather we observed a slight increase).

[7] http://chasen.org/˜taku/software/CRF++

[8] We also replaced the optimization module in the original package with that used in the Amis maximum entropy estimator (http://www-tsujii.is.s.u-tokyo.ac.jp/amis) since we encountered problems with the provided module in some cases.

[9] For the Gaussian parameter, we tested {13, 25, 50, 100, 200, 400, 800} (the accuracy did not change drastically among these values and it seems that there is no accuracy hump even if we use smaller values). We tested {500, 1000, 1414, 2000, 2828, 4000, 5657, 8000, 11313, 16000, 32000} for the margin parameters.

effects further.

6.2 Results

Table 2 compares the results. CRF outperformed the perceptron by a large margin. Although the averaged perceptron outperformed the perceptron, the improvement was slight. However, the margin perceptron greatly outperformed compared to the averaged perceptron. Yet, CRF still had the best baseline performance with only local features.

The proposed algorithm with non-local features improved the performance on the test set by 0.66 points over that of the margin perceptron without non-local features. The row "Candidate" refers to the candidate algorithm (Algorithm 4.1). From the results for the candidate algorithm, we can see that the modification part, (B), in Algorithm 4.2 was essential to make learning with non-local features effective.

We next examined the effect of n'. As can be seen from Table 3, an n' larger than that for training yields higher performance. The highest performance with the proposed algorithm was achieved when $n' = 6400$, where the improvement due to non-local features became 0.74 points.

The performance of the related work (Finkel et al., 2005; Krishnan and Manning, 2006) is listed in Table 4. We can see that the final performance of our algorithm was worse than that of the related work.

We changed the experimental setting slightly to investigate our algorithm further. Instead of the POS/chunk tags provided in the CoNLL 2003 dataset, we used the tags assigned by TagChunk (Daumé III and Marcu, 2005)[10] with the intention of using more accurate tags. The results with this setting are summarized in Table 5. Performance was better than that in the previous experiment for all algorithms. We think this was due to the quality of the POS/chunk tags. It is interesting that the effect of non-local features rose to 0.93 points with $n' = 6400$, even though the baseline performance was also improved. The resulting performance of the proposed algorithm with non-local features is higher than that of Finkel et al. (2005) and comparable with that of Krishnan and Manning (2006). This comparison, of course, is not fair because the setting was different. However, we think the results demonstrate a potential of our new algorithm.

Table 4: The performance of the related work.

Proposed ($n' = 6400$)	**92.54**	**87.17**	5657

The effect of BPM initialization was also examined. The number of BPM runs was 10 in this experiment. The performance of the proposed algorithm dropped from $91.95/86.30$ to $91.89/86.03$ without BPM initialization as expected in the setting of the experiment of Table 2. The performance of the margin perceptron, on the other hand, changed from $90.98/85.64$ to $90.98/85.90$ without BPM initialization. This result was unexpected from the result of our preliminary experiment. However, the performance was changed from $91.06/86.24$ to

Proposed ($n' = 100$)	92.23	87.04	28,880

$91.17/86.08$ (i.e., dropped for the evaluation set as expected), in the setting of the experiment of Table 5. Since the effect of BPM initialization is not conclusive only from these results, we need more experiments on this.

6.3 Comparison with re-ranking approach

Finally, we compared our algorithm with the reranking approach (Collins and Duffy, 2002; Collins, 2002b), where we first generate the n-best candidates using a model with only local features (the first model) and then re-rank the candidates using a model with non-local features (the second model).

We implemented two re-ranking models, "reranking 1" and "re-ranking 2". These models differ in how to incorporate the local information in the second model. "re-ranking 1" uses the score of the first model as a feature in addition to the non-local features as in Collins (2002b). "re-ranking 2" uses the same local features as the first model[11] in addition to the non-local features. The first models were trained using the margin perceptron algorithm in Algorithm 3.1. The second models were trained using the algorithm, which is obtained by replacing $\{\boldsymbol{y}^n\}$ with the n-best candidates by the first model. The first model used to generate n-best candidates for the development set and the test set was trained using the whole training data. However, CRFs or perceptrons generally have nearly zero error on the training data, although the first model should mis-label to some extent to make the training of the second model meaningful. To avoid this problem, we adopt cross-validation training as used in Collins (2002b). We split the training data into 5 sets. We then trained five first models using 4/5 of the data, each of which was used to generate n-best candidates for the remaining 1/5 of the data.

As in the previous experiments, we tuned C using the development set with $n' = 100$ and then tested other values for n'. Table 6 shows the results. As can be seen, re-ranking models were outperformed by our proposed algorithm, although they also outperformed the margin perceptron with only local features ("re-ranking 2" seems better than "re-ranking 1"). Table 7 shows the training time of each algorithm.[12] Our algorithm is much faster than the reranking approach that uses cross-validation training, while achieving the same or higher level of performance.

7 Discussion

As we mentioned, there are some algorithms similar to ours (Collins and Roark, 2004; Daumé III and Marcu, 2005; McDonald and Pereira, 2006; Liang et al., 2006). The differences of our algorithm from these algorithms are as follows.

Daumé III and Marcu (2005) presented the method called LaSO (Learning as Search Optimization), in which intractable exact inference is approximated by optimizing the behavior of the search process. The method can access non-local features at each search point, if their values can be determined from the search decisions already made. They provided robust training algorithms with guaranteed convergence for this framework. However, a difference is that our method can use non-local features whose value depends on all labels throughout training, and it is unclear whether the features whose values can only be determined at the end of the search (e.g., majority features) can be learned effectively with such an incremental manner of LaSO.

The algorithm proposed by McDonald and Pereira (2006) is also similar to ours. Their target was non-projective dependency parsing, where exact inference is intractable. Instead of using

[11] The weights were re-trained for the second model.

[12] Training time was measured on a machine with 2.33 GHz QuadCore Intel Xeons and 8 GB of memory. C was fixed to 5657.

n-best/re-scoring approach as ours, their method modifies the single best projective parse, which can be found efficiently, to find a candidate with higher score under non-local features. Liang et al. (2006) used n candidates of a beam search in the Collins' perceptron algorithm for machine translation. Collins and Roark (2004) proposed an approximate incremental method for parsing. Their method can be used for sequence labeling as well. These studies, however, did not explain the validity of their updating methods in terms of convergence.

To achieve robust training, Daumé III and Marcu (2005) employed the averaged perceptron (Collins, 2002a) and ALMA (Gentile, 2001). Collins and Roark (2004) used the averaged perceptron (Collins, 2002a). McDonald and Pereira (2006) used MIRA (Crammer et al., 2006). On the other hand, we employed the margin perceptron (Krauth and Mézard, 1987), extending it to sequence labeling. We demonstrated that this greatly improved robustness.

With regard to the local update, (B), in Algorithm 4.2, "early updates" (Collins and Roark, 2004) and "y-good" requirement in (Daumé III and Marcu, 2005) resemble our local update in that they tried to avoid the situation where the correct answer cannot be output. Considering such commonality, the way of combining the local update and the non-local update might be one important key for further improvement.

It is still open whether these differences are advantages or disadvantages. However, we think our algorithm can be a contribution to the study for incorporating non-local features. The convergence guarantee is important for the confidence in the training results, although it does not mean high performance directly. Our algorithm could at least improve the accuracy of NER with non-local features and it was indicated that our algorithm was superior to the re-ranking approach in terms of accuracy and training cost. However, the achieved accuracy was not better than that of related work (Finkel et al., 2005; Krishnan and Manning, 2006) based on CRFs. Although this might indicate the limitation of perceptron-based methods, it has also been shown that there is still room for improvement in perceptron-based algorithms as our margin perceptron algorithm demonstrated.

8 Conclusion

In this paper, we presented a new perceptron algorithm for learning with non-local features. We think the proposed algorithm is an important step towards achieving our final objective. We would like to investigate various types of new non-local features using the proposed algorithm in future work.

Appendix A: Convergence of Algorithm 4.2

Let $\boldsymbol{\alpha}^k$ be a weight vector before the kth update and ϵ_k be a variable that takes 1 when the kth update is done in (A) and 0 when done in (B). The update rule can then be written as $\boldsymbol{\alpha}^{k+1} = \boldsymbol{\alpha}^k + \epsilon_k(\Phi^{a*} - \Phi^a + (1-\epsilon_k)(\Phi^{l*} - \Phi^l)$.[13] First, we obtain

$$\begin{aligned}\boldsymbol{\alpha}^{k+1}\cdot\boldsymbol{U}^l &= \boldsymbol{\alpha}^k\cdot\boldsymbol{U}^l + \epsilon_k(\Phi^{a*}\cdot\boldsymbol{U}^l - \Phi^a\cdot\boldsymbol{U}^l)\\ &\quad +(1-\epsilon_k)(\Phi^{l*}\cdot\boldsymbol{U}^l - \Phi^l\cdot\boldsymbol{U}^l)\\ &\geq \boldsymbol{\alpha}^k\cdot\boldsymbol{U}^l + \epsilon_k\delta + (1-\epsilon_k)\delta\\ &= \boldsymbol{\alpha}^k\cdot\boldsymbol{U}^l + \delta \geq \boldsymbol{\alpha}^1\cdot\boldsymbol{U}^l + k\delta = k\delta\end{aligned}$$

Therefore, $(k\delta)^2 \leq (\boldsymbol{\alpha}^{k+1}\cdot\boldsymbol{U}^l)^2 \leq (||\boldsymbol{\alpha}^{k+1}||||\boldsymbol{U}^l||)^2 = ||\boldsymbol{\alpha}^{k+1}||^2$ — (1). On the other hand, we also obtain

$$\begin{aligned}||\boldsymbol{\alpha}^{k+1}||^2 &\leq ||\boldsymbol{\alpha}^k||^2 + 2\epsilon_k\boldsymbol{\alpha}^k(\Phi^{a*} - \Phi^a)\\ &\quad +2(1-\epsilon_k)\boldsymbol{\alpha}^k(\Phi^{l*} - \Phi^l)\\ &\quad +\{\epsilon_k(\Phi^{a*} - \Phi^a) + (1-\epsilon_k)(\Phi^{l*} - \Phi^l)\}^2\\ &\leq ||\boldsymbol{\alpha}^k||^2 + 2C + R^2\\ &\leq ||\boldsymbol{\alpha}^1||^2 + k(R^2+2C) = k(R^2+2C) \text{— (2)}\end{aligned}$$

We used $\boldsymbol{\alpha}^k(\Phi^{a*} - \Phi^a) \leq C^a$, $\boldsymbol{\alpha}^k(\Phi^{l*} - \Phi^l) \leq C^l$ and $C^l = C^a = C$ to derive $2C$ in the second inequality. We used $||\Phi^{l*} - \Phi^l|| \leq ||\Phi^{a*} - \Phi^a|| \leq R$ to derive R^2.

Combining (1) and (2), we obtain $k \leq (R^2 + 2C)/\delta^2$. Substituting this into (2) gives $||\boldsymbol{\alpha}^k|| \leq (R^2+2C)/\delta$. Since $\boldsymbol{y}* = \boldsymbol{y}'$ and $\Phi^{a*}\cdot\boldsymbol{\alpha} - \Phi^{a''}\cdot\boldsymbol{\alpha} > C$ after convergence, we obtain

$$\gamma'(\boldsymbol{\alpha}) = \min_{\boldsymbol{x}_i}\frac{\Phi^{a*}\cdot\boldsymbol{\alpha} - \Phi^{a''}\cdot\boldsymbol{\alpha}}{||\boldsymbol{\alpha}||} \geq C\delta/(2C+R^2).$$

[13] We use the shorthand $\Phi^{a*} = \Phi^a(\boldsymbol{x}_i, \boldsymbol{y}_i^*)$, $\Phi^a = \Phi^a(\boldsymbol{x}_i, \boldsymbol{y})$, $\Phi^{l*} = \Phi^l(\boldsymbol{x}_i, \boldsymbol{y}_i^*)$, and $\Phi^l = \Phi^l(\boldsymbol{x}_i, \boldsymbol{y})$ where $\boldsymbol{y}$ represents the candidate used to update ($\boldsymbol{y}'$, $\boldsymbol{y}''$, $\boldsymbol{y}^1$, or $\boldsymbol{y}^2$).

Abstract

In this paper, we address a unique problem in Chinese language processing and report on our study on extending a Chinese thesaurus with *region-specific* words, mostly from the financial domain, from various Chinese speech communities. With the larger goal of automatically constructing a Pan-Chinese lexical resource, this work aims at taking an existing semantic classificatory structure as leverage and incorporating new words into it. In particular, it is important to see if the classification could accommodate new words from heterogeneous data sources, and whether simple similarity measures and clustering methods could cope with such variation. We use the cosine function for similarity and test it on automatically classifying 120 target words from four regions, using different datasets for the extraction of feature vectors. The automatic classification results were evaluated against human judgement, and the performance was encouraging, with accuracy reaching over 85% in some cases. Thus while human judgement is not straightforward and it is difficult to create a Pan-Chinese lexicon manually, it is observed that combining simple clustering methods with the appropriate data sources appears to be a promising approach toward its automatic construction.

1 Introduction

Large-scale semantic lexicons are important resources for many natural language processing (NLP) tasks. For a significant world language such as Chinese, it is especially critical to capture the substantial *regional variation* as an important part of the lexical knowledge, which will be useful for many NLP applications, including natural language understanding, information retrieval, and machine translation. Existing Chinese lexical resources, however, are often based on language use in one particular region and thus lack the desired comprehensiveness.

Toward this end, Tsou and Kwong (2006) proposed a comprehensive Pan-Chinese lexical resource, based on a large and unique synchronous Chinese corpus as an authentic source for lexical acquisition and analysis across various Chinese speech communities. To allow maximum *versatility* and *portability*, it is expected to document the core and universal substances of the language on the one hand, and also the more subtle variations found in different communities on the other. Different Chinese speech communities might share lexical items in the same form but with different meanings. For instance, the word 居屋 refers to general housing in Mainland China but specifically to housing under the Home Ownership Scheme in Hong Kong; and while the word 住房 is similar to 居屋 to mean general housing in Mainland China, it is rarely seen in the Hong Kong context.

Hence, the current study aims at taking an existing Chinese thesaurus, namely the *Tongyici Cilin* 同義詞詞林, as leverage and extending it with lexical items specific to individual Chinese speech communities. In particular, the feasibility depends on the following issues: (1) Can lexical items from various Chinese speech communities, that is, from such heterogeneous sources, be classified as effectively with methods shown to work for clustering

Proceedings of the 2007 Joint Conference on Empirical Methods in Natural Language Processing and Computational Natural Language Learning, pp. 325–333, Prague, June 2007. ©2007 Association for Computational Linguistics

closely related words from presumably the same, or homogenous, source? (2) Could existing semantic classificatory structures accommodate concepts and expressions specific to individual Chinese speech communities?

Measuring similarity will make sense only if the feature vectors of the two words under comparison are directly comparable. There is usually no problem if both words and their contextual features are from the same data source. Since Tongyici Cilin (or simply Cilin hereafter) is based on the vocabulary used in Mainland China, it is not clear how often these words will be found in data from other places, and even if they are found, how well the feature vectors extracted could reflect the expected usage or sense. Our hypothesis is that it will be more effective to classify new words from Mainland China with respect to Cilin categories, than to do the same on new words from regions outside Mainland China. Furthermore, if this hypothesis holds, one would need to consider separate mechanisms to cluster heterogeneous region-specific words in the Pan-Chinese context.

Thus in the current study we sampled 30 target words specific to each of Beijing, Hong Kong, Singapore, and Taipei, from the financial domain; and used the cosine similarity function to classify them into one or more of the semantic categories in Cilin. The automatic classification results were compared with a simple baseline method, against human judgement as the gold standard. In general, an accuracy of up to 85% could be reached with the top 15 candidates considered. It turns out that our hypothesis is supported by the Taipei test data, whereas the data heterogeneity effect is less obvious in Hong Kong and Singapore test data, though the effect on individual test items varies.

In Section 2, we will briefly review related work and highlight the innovations of the current study. In Sections 3 and 4, we will describe the materials used and the experimental setup respectively. Results will be presented and discussed with future directions in Section 5, followed by a conclusion in Section 6.

2 Related Work

To build a semantic lexicon, one has to identify the relation between words within a semantic hierarchy, and to group similar words together into a class. Previous work on automatic methods for building semantic lexicons could be divided into two main groups. One is automatic thesaurus acquisition, that is, to identify synonyms or topically related words from corpora based on various measures of similarity (e.g. Riloff and Shepherd, 1997; Thelen and Riloff, 2002). For instance, Lin (1998) used dependency relation as word features to compute word similarities from large corpora, and compared the thesaurus created in such a way with WordNet and Roget classes. Caraballo (1999) selected head nouns from conjunctions and appositives in noun phrases, and used the cosine similarity measure with a bottom-up clustering technique to construct a noun hierarchy from text. Curran and Moens (2002) explored a new similarity measure for automatic thesaurus extraction which better compromises with the speed/performance tradeoff. You and Chen (2006) used a feature clustering method to create a thesaurus from a Chinese newspaper corpus.

Another line of research, which is more closely related with the current study, is to extend existing thesauri by classifying new words with respect to their given structures (e.g. Tokunaga *et al.*, 1997; Pekar, 2004). An early effort along this line is Hearst (1992), who attempted to identify hyponyms from large text corpora, based on a set of lexico-syntactic patterns, to augment and critique the content of WordNet. Ciaramita (2002) compared several models in classifying nouns with respect to a simplified version of WordNet and signified the gain in performance with morphological features. For Chinese, Tseng (2003) proposed a method based on morphological similarity to assign a Cilin category to unknown words from the Sinica corpus which were not in the Chinese Electronic Dictionary and Cilin; but somehow the test data were taken from Cilin, and therefore could not really demonstrate the effectiveness with unknown words found in the Sinica corpus.

The current work attempts to classify new words with an existing thesaural classificatory structure. However, the usual practice in past studies is to test with a portion of data from the thesaurus itself and evaluate the results against the original classification of those words. This study is thus different in the following ways: (1) The test data (i.e. the target words to be classified) were not taken from the thesaurus, but extracted from corpora and these words were unknown to the thesaurus. (2) The target words were not limited to nouns. (3) Automatic classification results were compared with a baseline method and with the manual judgement of several linguistics students constituting the gold standard. (4) In view of the heterogeneous nature of the Pan-Chinese context, we experimented with extracting feature vectors from different datasets.

3 Materials

3.1 The Tongyici Cilin

The Tongyici Cilin (同義詞詞林) (Mei *et al.*, 1984) is a Chinese synonym dictionary, or more often known as a Chinese thesaurus in the tradition of the Roget's Thesaurus for English. The Roget's Thesaurus has about 1,000 numbered semantic heads, more generally grouped under higher level semantic classes and subclasses, and more specifically differentiated into paragraphs and semicolon-separated word groups. Similarly, some 70,000 Chinese lexical items are organized into a hierarchy of broad conceptual categories in Cilin. Its classification consists of 12 top-level semantic classes, 94 subclasses, 1,428 semantic heads and 3,925 paragraphs. It was first published in the 1980s and was based on lexical usages mostly of post-1949 Mainland China. The Appendix shows some example subclasses. In the following discussion, we will mainly refer to the subclass level and semantic head level.

3.2 The LIVAC Synchronous Corpus

LIVAC (http://www.livac.org) stands for Linguistic Variation in Chinese Speech Communities. It is a synchronous corpus developed and dynamically maintained by the Language Information Sciences Research Centre of the City University of Hong Kong since 1995 (Tsou and Lai, 2003). The corpus consists of newspaper articles collected regularly and synchronously from six Chinese speech communities, namely Hong Kong, Beijing, Taipei, Singapore, Shanghai, and Macau. Texts collected cover a variety of domains, including front page news stories, local news, international news, editorials, sports news, entertainment news, and financial news. Up to December 2006, the corpus has already accumulated over 200 million character tokens which, upon automatic word segmentation and manual verification, amount to over 1.2 million word types.

For the present study, we made use of the subcorpora collected over the 9-year period 1995-2004 from Beijing (BJ), Hong Kong (HK), Singapore (SG), and Taipei (TW). In particular, we made use of the *financial news* sections in these subcorpora, from which we extracted feature vectors for comparing similarity between a given target word and a thesaurus class, which is further explained in Section 4.3. Table 1 shows the sizes of the subcorpora.

3.3 Test Data

Instead of using a portion of Cilin as the test data, we extracted unique lexical items from the various subcorpora above, and classified them with respect to the Cilin classification.

Kwong and Tsou (2006) observed that among the unique lexical items found from the individual subcorpora, only about 30-40% are covered by Cilin, but not necessarily in the expected senses. In other words, Cilin could in fact be enriched with over 60% of the unique items from various regions.

In the current study, we sampled the most frequent 30 words from each of these unique item lists for testing. Classification was based on their similarity with each of the Cilin subclasses, compared by the cosine measure, as discussed in Section 4.3.

Subcorpus	**Size of Financial News Sections** (rounded to nearest 1K)	
	Word Token	**Word Type**
BJ	232K	20K
HK	970K	38K
SG	621K	28K
TW	254K	22K

Table 1 Sizes of Individual Subcorpora

4 Experiments

4.1 Human Judgement

Three undergraduate linguistics students and one research student on computational linguistics from the City University of Hong Kong were asked to do the task. The undergraduate students were raised in Hong Kong and the research student in Mainland China. They were asked to assign what they consider the most appropriate Cilin category (up to the semantic head level, i.e. third level in the

Cilin structure) to each of the 120 target words. The inter-annotator agreement was measured by the *Kappa* statistic (Siegel and Castellan, 1988), at both the subclass and semantic head levels. Results on the human judgement are discussed in Section 5.1.

4.2 Creating Gold Standard

The "gold standard" was set at both the subclass level and semantic head level. For each level, we formed a "strict" standard for which we considered all categories assigned by at least two judges to a word; and a "loose" standard for which we considered all categories assigned by one or more judges. For evaluating the automatic classification in this study, however, we only experimented with the loose standard at the subclass level.

4.3 Automatic Classification

Each target word was automatically classified with respect to the Cilin subclasses based on the similarity between the target word and each subclass.

We compute the similarity by the cosine between the two corresponding feature vectors. The feature vector of a given target word contains *all its co-occurring content words* in the corpus within a window of ±5 words (excluding many general adjectives and adverbs, and numbers and proper names were all ignored). The feature vector of a Cilin subclass is based on the union of the features (i.e. co-occurring words in the corpus) from all individual members in the subclass.

The cosine of two feature vectors is computed as

$$\cos(\vec{v}, \vec{w}) = \frac{\vec{v} \cdot \vec{w}}{|\vec{v}||\vec{w}|}$$

In view of the difference in the feature space of a target word and a whole class of words, and thus the potential difference in the number of occurrence of individual features, we experimented with two versions of the cosine measurement, namely binary vectors and real-valued vectors.

In addition, as mentioned in previous sections, we also experimented with the following conditions: whether feature vectors for the Cilin subclasses were extracted from the subcorpus where a given target word originates, or from the Beijing subcorpus which is assumed to be representative of language use in Mainland China. All automatic classification results were evaluated against the gold standard based on human judgement.

4.4 Baseline

To evaluate the effectiveness of the automatic classification, we adopted a simple baseline measure by ranking the 94 subclasses in descending order of the number of words they cover. In other words, assuming the bigger the subclass size, the more likely it covers a new term, thus we compared the top-ranking subclasses with the classifications obtained from the automatic method using the cosine measure.

5 Results and Discussion

5.1 Response from Human Judges

All human judges reported difficulties in various degrees in assigning Cilin categories to the target words. The major problem comes from the regional specificity and thus the unfamiliarity of the judges with the respective lexical items and contexts. For instance, students grown up in Hong Kong were most familiar with the Hong Kong data, and slightly less so with the Beijing data, but more often had the least ideas for the Taipei and Singapore data. The research student from Mainland China had no problem with Beijing data and the lexical items in Cilin, but had a hard time figuring out the meaning for words from Hong Kong, Taipei and Singapore. For example, all judges reported problem with the term 自撮, one of the target words from Singapore referring to 自撮股市 (CLOB in the Singaporean stock market), which is really specific to Singapore.

The demand on cross-cultural knowledge thus poses a challenge for building a Pan-Chinese lexical resource manually. Cilin, for instance, is quite biased in language use in Mainland China, and it requires experts with knowledge of a wide variety of Chinese terms to be able to manually classify lexical items specific to other Chinese speech communities. It is therefore even more important to devise robust ways for automatic acquisition of such a resource.

Notwithstanding the difficulty, the inter-annotator agreement was quite satisfactory. At the subclass level, we found *K*=0.6870. At the semantic head level, we found *K*=0.5971. Both figures are statistically significant.

5.2 Gold Standard

As mentioned, we set up a loose standard and a strict standard at both the subclass and semantic head level. In general, the judges managed to reach some consensus in all cases, except for two words from Singapore. For these two cases, we considered all categories assigned by any of the judges for both standards.

The gold standards were verified by the authors. Although in several cases the judges did not reach complete agreement with one another, we found that their decisions reflected various possible perspectives to classify a given word with respect to the Cilin classification; and the judges' assignments, albeit varied, were nevertheless reasonable in one way or another.

5.3 Evaluating Automatic Classification

In the following discussion, we will refer to the various testing conditions for each group of target words with labels in the form of Cos-<Vector Type>-<Target Words>-<Cilin Feature Source>. Thus the label Cos-Bin-hk-hk means testing on Hong Kong target words with binary vectors and extracting features for the Cilin words from the Hong Kong subcorpus; and the label Cos-RV-sg-bj means testing on Singapore target words with real-valued vectors and extracting features for the Cilin words from the Beijing subcorpus. For each target word, we evaluated the automatic classification (and the baseline ranking) by matching the human decisions with the top N candidates. If any of the categories suggested by the human judges is covered, the automatic classification is considered accurate. The results are shown in Figure 1 for test data from individual regions.

Overall speaking, the results are very encouraging, especially in view of the number of categories (over 90) we have at the subclass level. An accuracy of 80% or more is obtained in general if the top 15 candidates were considered, which is much higher than the baseline result in all cases. Table 2 shows some examples with appropriate classification within the Top 3 candidates. The two-letter codes in the "Top 3" column in Table 2 refer to the subclass labels, and the code in bold is the one matching human judgement.

In terms of the difference between binary vectors and real-valued vectors in the similarity measurement, the latter almost always gave better results. This was not surprising as we expected by using real-valued vectors we could be less affected by the potential huge difference in the feature space and the number of occurrence of the features for a Cilin subclass and a target word.

As for extracting features for Cilin subclasses from the Beijing subcorpus or other subcorpora, the difference is more obvious for the Singapore and Taipei target words. We will discuss the results for each group of target words in detail below.

5.4 Performance on Individual Sources

Target words from Beijing were expected to have a relatively higher accuracy because they are homogenous with the Cilin content. It turned out, however, the accuracy only reached 73% with top 15 candidates and 83% with top 20 candidates even under the Cos-RV-bj-bj condition. Words like 非典 (SARS), 節水 (save water), 產業化 (industrialize / industrialization), 合格率 (passing rate) and 傳銷 (multi-level marketing) could not be successfully classified.

Results were surprisingly good for target words from the Hong Kong subcorpus. Under the Cos-RV-hk-hk condition, the accuracy was 87% with top 15 candidates and even over 95% with top 20 candidates considered. Apart from this high accuracy, another unexpected observation is the lack of significant difference between Cos-RV-hk-hk and Cos-RV-hk-bj. One possible reason is that the relatively larger size of the Hong Kong subcorpus might have allowed enough features to be extracted even for the Cilin words. Nevertheless, the similar results from the two conditions might also suggest that the context in which Cilin words are used might be relatively similar in the Hong Kong subcorpus and the Beijing subcorpus, as compared with other communities.

Similar trends were observed from the Singapore target words. Looking at Cos-RV-sg-sg and Cos-RV-sg-bj, it appears that extracting feature vectors for the Cilin words from the Singapore subcorpus leads to better performance than extracting them from the Beijing subcorpus. It suggests that although the Singapore subcorpus shares those words in Cilin, the context in which they are used might be slightly different from their use in Mainland China. Thus extracting their contextual features from the Singapore subcorpus might better reflect their usage and makes it more comparable with the unique target words from Singapore. Such possible difference in contextual features with shared lexical items between different Chinese speech communities would require further investigation, and will form part of our future work as discussed below. Despite the above observation from the accuracy figures, the actual effect, however, seems to vary on individual lexical items. Table 3 shows some examples of target words which received similar (with white cells) and very different (with shaded cells) classification respectively under the two conditions. It appears that the region-specific but common concepts like 寫字樓 (office), 組屋 (apartment), 私宅 (private residence), which relate to building or housing, were affected most.

Taipei data, on the contrary, seems to be more affected by the different testing conditions. Cos-Bin-tw-bj and Cos-RV-tw-bj produced similar results, and both conditions showed better results than Cos-RV-tw-tw. This supports our hypothesis that the effect of data heterogeneity is so apparent that it is much harder to classify target words unique to Taipei with respect to the Cilin categories. In addition, as Kwong and Tsou (2006) observed, Beijing and Taipei data share the least number of lexical items, among the four regions under investigation. Hence, words in Cilin might not have the appropriate contextual feature vectors extracted from the Taipei subcorpus.

The different results for individual regions might be partly due to the endocentric and exocentric nature of influence in lexical innovation (e.g. Tsou, 2001) especially with respect to the financial domain and the history of capitalism in individual regions. This factor is worth further investigation.

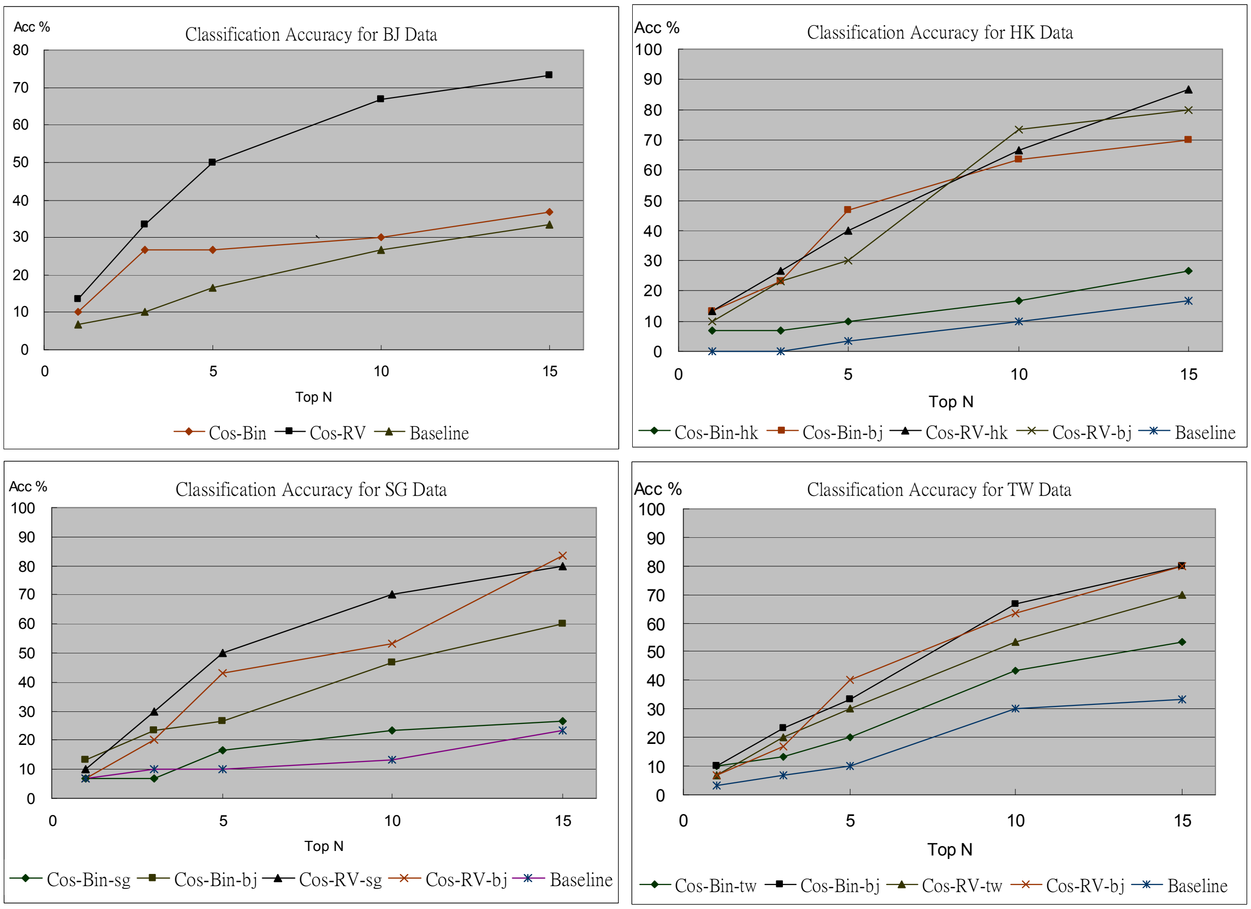

Figure 1 Classification Results with Top N Candidates

No.	Region	Word	Top 3
1	BJ	退耕還林	**Di** Gb Df

Table 2 Examples of Correct Classification (Top 3)[1]

5.5 General Discussions and Future Work

As mentioned in a previous section, the test data in this study were not taken from the thesaurus itself, but were unknown words to the thesaurus. They were extracted from corpora, and were not limited to nouns. We found in this study that the simple cosine measure, which used to be applied for clustering contextually similar words from homogenous sources, performs quite well in general for classifying these unseen words with respect to the Cilin subclasses. The automatic classification results were compared with the manual judgement of several linguistics students. In addition to providing a gold standard for evaluating the automatic classification results in this study, the human judgement on the one hand proves that the Cilin classificatory structure could accommodate region-specific lexical items; but on the other hand also suggests how difficult it would be to construct such a Pan-Chinese lexicon manually as rich cultural and linguistic knowledge would be required. Moreover, we started with Cilin as the established semantic classification and attempted to classify words specific to Beijing, Hong Kong, Singapore, and Taipei respectively. The heterogeneity of sources did not seem to hamper the similarity measure on the whole, provided appropriate datasets are used for feature extraction, although the actual effect seemed to vary on individual lexical items.

No.	Source	Word	Ranking of 1st appropriate class	
			Cos-RV-hk-hk, etc.	Cos-RV-hk-bj, etc.
1	HK	銷情	1	1
2	HK	寬頻	1	1
3	HK	紅籌	1	1
4	HK	加推	2	10
5	HK	低位	19	5
6	HK	寫字樓	13	30
7	SG	財政年	2	2
8	SG	賣空	2	1
9	SG	附加股	5	4
10	SG	組屋	1	12
11	SG	容積率	1	9
12	SG	私宅	8	26
13	TW	存底	1	1
14	TW	個股	4	3
15	TW	金控	5	1
16	TW	投信	18	4
17	TW	成長率	12	5
18	TW	現金卡	8	2

Table 3 Different Impact on Individual Items[2]

Despite the encouraging results with the top 15 candidates in the current study, it is desirable to improve the accuracy for the system to be useful in

[1] English gloss: 1-restoring agricultural lands for afforestation, 2-material, 3-coal mine, 4-to seize (an opportunity), 5-unemployed, 6-sales performance, 7-broadband, 8-red chip, 9-interest rate, 10-property stocks, 11-financial year, 12-sell short, 13-proposal, 14-sell, 15-brigadier general, 16-financial holdings, 17-individual stocks, 18-property market, 19-cash card, 20-stub.

[2] English gloss: 1-sales performance, 2-broadband, 3-red chip, 4-add (supply to market), 5-low level, 6-office, 7-financial year, 8-sell short, 9-rights issue, 10-apartment, 11-holding space rate, 12-private residence, 13-stub, 14-individual stocks, 15-financial holdings, 16-investment trust, 17-growth rate, 18-cash card.

practice. Hence our next step is to expand the test data size and to explore alternative methods such as using a nearest neighbour approach. In addition, we plan to further the investigation in the following directions. First, we will experiment with the automatic classification at the Cilin semantic head level, which is much more fine-grained than the subclasses. The fine-grainedness might make the task more difficult, but at the same time the more specialized grouping might pose less ambiguity for classification. Second, we will further experiment with classifying words from other special domains like sports, as well as the general domain. Third, we will study the classification in terms of the part-of-speech of the target words, and their respective requirements on the kinds of features which give best classification performance.

The current study only dealt with presumably Modern Standard Chinese in different communities, and it could potentially be expanded to handle various dialects within a common resource, eventually benefiting speech lexicons and applications at large.

6 Conclusion

In this paper, we have reported our study on a unique problem in Chinese language processing, namely extending a Chinese thesaurus with new words from various Chinese speech communities, including Beijing, Hong Kong, Singapore and Taipei. The critical issues include whether the existing classificatory structure could accommodate concepts and expressions specific to various Chinese speech communities, and whether the difference in textual sources might pose difficulty in using conventional similarity measures for the automatic classification. Our experiments, using the cosine function to measure similarity and testing with various sources for extracting contextual vectors, suggest that the classification performance might depend on the compatibility between the words in the thesaurus and the sources from which the target words are drawn. Evaluated against human judgement, an accuracy of over 85% was reached in some cases, which were much higher than the baseline and were very encouraging in general. While human judgement is not straightforward and it is difficult to create a Pan-Chinese lexicon manually, combining simple classification methods with the appropriate data sources seems to be a promising approach toward its automatic construction.

Abstract

Product reviews posted at online shopping sites vary greatly in quality. This paper addresses the problem of detecting low-quality product reviews. Three types of biases in the existing evaluation standard of product reviews are discovered. To assess the quality of product reviews, a set of specifications for judging the quality of reviews is first defined. A classification-based approach is proposed to detect the low-quality reviews. We apply the proposed approach to enhance opinion summarization in a two-stage framework. Experimental results show that the proposed approach effectively (1) discriminates low-quality reviews from high-quality ones and (2) enhances the task of opinion summarization by detecting and filtering low-quality reviews.

1 Introduction

In the past few years, there has been an increasing interest in mining opinions from product reviews (Pang, et al, 2002; Liu, et al, 2004; Popescu and Etzioni, 2005). However, due to the lack of editorial and quality control, reviews on products vary greatly in quality. Thus, it is crucial to have a mechanism capable of assessing the quality of reviews and detecting low-quality/noisy reviews.

Some shopping sites already provide a function of assessing the quality of reviews. For example, Amazon[1] allows users to vote for the helpfulness of each review and then ranks the reviews based on the accumulated votes. However, according to our survey in Section 3, users' votes at Amazon have three kinds of biases as follows: (1) *imbalance vote bias,* (2) *winner circle bias, and* (3) *early bird bias.* Existing studies (Kim et al, 2006; Zhang and Varadarajan, 2006) used these users' votes for training ranking models to assess the quality of reviews, which therefore are subject to these biases.

In this paper, we demonstrate the aforementioned biases and define a standard specification to measure the quality of product reviews. We then manually annotate a set of ground-truth with real world product review data conforming to the specification.

To automatically detect low-quality product reviews, we propose a classification-based approach learned from the annotated ground-truth. The proposed approach explores three aspects of product reviews, namely informativeness, readability, and subjectiveness.

We apply the proposed approach to opinion summarization, a typical opinion mining task. The proposed approach enhances the existing work in a two-stage framework, where the low-quality review detection is applied right before the summarization stage.

Experimental results show that the proposed approach can discriminate low-quality reviews from high-quality ones effectively. In addition, the task of opinion summarization can be enhanced by detecting and filtering low-quality reviews.

The rest of the paper is organized as follows: Section 2 introduces the related work. In Section 3, we define the quality of product reviews. In Section 4, we present our approach to detecting low-quality reviews. In Section 5, we empirically verify the effectiveness of the proposed approach and its use for opinion summarization. Section 6 summarizes our work in this paper and points out the future work.

2 Related Work

2.1 Evaluating Helpfulness of Reviews

The problem of *evaluating helpfulness of reviews* (Kim et al, 2006), also known as *learning utility of reviews* (Zhang and Varadarajan, 2006), is quite similar to our problem of *assessing the quality of reviews*.

In practice, researchers in this area considered the problem as a ranking problem and solved it with regression models. In the process of model training and testing, they used the ground-truth derived from users' votes of helpfulness provided by Amazon. As we will show later in Section 3, these models all suffered from three types of voting bias.

In our work, we avoid using users' votes by developing a specification on the quality of reviews and building a ground-truth according to the specification.

2.2 Mining Opinions from Reviews

One area of research on opinion mining from product reviews is to judge whether a review expresses a positive or a negative opinion. For example, Turney (2006) presented a simple unsupervised learning algorithm in judging reviews as “thumbs up” (recommended) or “thumbs down” (not recommended). Pang et al (2002) considered the same problem and presented a set of supervised machine learning approaches to it. For other work see also Dave et al. (2003), Pang and Lee (2004, 2005).

Another area of research on opinion mining is to extract and summarize users' opinions from product reviews (Hu and Liu, 2004; Liu et al., 2005; Popescu and Etzioni, 2005). Typically, a sentence or a text segment in the reviews is treated as the basic unit. The polarity of users' sentiments on a product feature in each unit is extracted. Then the aggregation of the polarities of individual sentiments is presented to users so that they can have an at-a-glance view on how other experienced users rated on a certain product. The major weakness in the existing studies is that all the reviews, including low-quality ones, are taken into consideration and treated equally for generating the summary. In this paper, we enhance the application by detecting and filtering low-quality reviews. In order to achieve that, we first define what the quality of reviews is.

3 Quality of Product Reviews

In this section, we will first show three biases of users' votes observed on Amazon, and then present our specification on the *quality of product reviews*.

3.1 Amazon Ground-truth

In our study, we use the product reviews on digital cameras crawled from Amazon as our data set. The data set consists of 23,141 reviews on 946 digital cameras. At the Amazon site, users could vote for a review with a “helpful” or “unhelpful” label. Thus, for each review there are two numbers indicating the statistics of these two labels, namely the number of “helpful” votes and that of “unhelpful” ones. Kim et al (2006) used the percentage of “helpful” votes as the measure of evaluating the “quality of reviews” in their experiments. We call the ground-truth based on this measure as “Amazon ground-truth”.

Certainly, the ground-truth has the advantage of convenience. However, we identify three types of biases that make the Amazon ground-truth not always suitable for determining the quality of reviews. We describe these biases in details in the rest of this section.

3.1.1 Imbalance Vote Bias

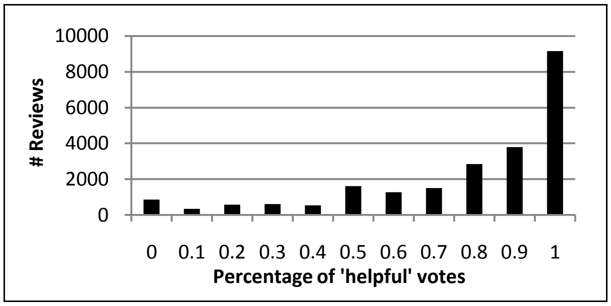

Figure 1. Reviews' percentage scores

At the Amazon site, users tend to value others' opinions positively rather than negatively. From Figure 1, we can see that a half of the 23,141 reviews (corresponding to the two bars on the right of the figure) have more than 90% "helpful" votes, including 9,100 reviews with 100% "helpful" votes. From an in-depth investigation on these highly-voted reviews, we observed that some did not really have as good quality as the votes hint. For example, in Figure 2, the review about *Canon PowerShot S500* receives 40 "helpful" votes out of 40 votes although it only gives very brief description on the product features in its second paragraph. We call this type of bias "imbalance vote" bias.

> *This is my second Canon digital elph camera. Both were great cameras. Recently upgraded to the S500. About 6 months later I get the dreaded E18 error. I searched the Internet and found numerous people having problems. When I determined the problem to be the lens not fully extending I decided to give it a tug. It clicked and the camera came on, ready to take pictures. Turning it off and on produced the E18 again. While turning it on I gave it a nice little bump on the side (where the USB connector is) and the lens popped out on its own. No problems since.*
>
> *It's a nice compact and light camera and takes great photos and videos. Only complaint (other than E18) is the limit of 30-second videos on 640x480 mode. I've got a 512MB compact flash card, I should be able to take as much footage as I have memory in one take.*

Figure 2. An example review

3.1.2 Winner Circle Bias

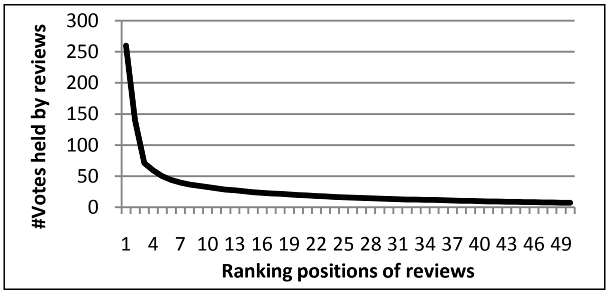

Figure 3. Votes of the top-50 ranked reviews

There also exists a bootstrapping effect of "hot" reviews at the Amazon site. Figure 3 shows the "helpful" votes for the top 50 ranked reviews. The numbers are averaged over 127 digital cameras which have no less than 50 reviews. As shown in this figure, the top two reviews hold more than 250 and 140 votes respectively on average; while the numbers of votes held by lower-ranked reviews decrease exponentially. This is so-called the "winner circle" bias: the more votes a review gains, the more default authority it would appear to the readers, which in turn will influence the objectivity of the readers' votes. Also, the higher ranked reviews would attract more eyeballs and therefore gain more people's votes. This mutual influence among labelers should be avoided when the votes are used as the evaluation standard.

3.1.3 Early Bird Bias

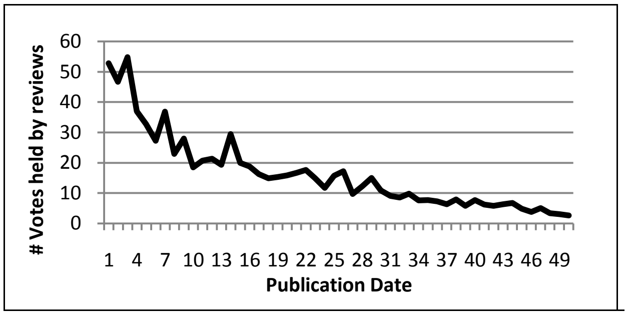

Figure 4. Dependency on publication date

Publication date can influence the accumulation of users' votes. In Figure 4, the *n*'*th* publication date represents the *n*'*th* month after the product is released. The number in the figure is averaged over all the digital cameras in the data set. We can observe a clear trend that the earlier a review is posted, the more votes it will get. This is simply because reviews posted earlier are exposed to users for a longer time. Therefore, some high quality reviews may get fewer users' vote because of later publication. We call this "early bird" bias.

3.2 Specification of Quality

Besides these aforementioned biases, using the raw rating from readers directly also fails to provide a clear guideline for what a good review consists of. In this section, we provide such a guideline, which we name as the specification (SPEC).

In the SPEC, we define four categories of review quality which represent different values of the reviews to users' purchase decision: "best review", "good review", "fair review", and "bad review". A generic description of the SPEC is as follows:

A *best* review must be a rather complete and detailed comment on a product. It presents several aspects of a product and provides convincing opinions with enough evidence. Usually a best review could be taken as the main reference that users only need to read before making their purchase decision on a certain product. The first review in Figure 5 is a *best* review. It presents several product features and provides convincing opinions with sufficient evidence. It is also in a good format for readers to easily understand. Note that we omit some words in the example to save the space.

A *good* review is a relatively complete comment on a product, but not with as much supporting evidence as necessary. It could be used as a strong and influential reference, but not as the only recommendation. The second review in Figure 5 is such an example.

A *fair* review contains a very brief description on a product. It does not supply detailed evaluation on the product, but only comments on some aspects of the product. For example, the third review in Figure 5 mainly talks about "*the delay between pictures*", but less about other aspects of the camera.

A *bad* review is usually an incorrect description of a product with misleading information. It talks little about a specific product but much about some general topics (e.g. photography). For example, the last review in Figure 5 talks about the topic of "*generic battery*", but does not specify any digital camera. A bad review is an "unhelpful" review that can be ignored.

Best Review:

I purchased this camera about six months ago after my Kodak Easyshare camera completely died on me. I did a little research and read only good things about this Canon camera so I decided to go with it because it was very reasonably priced (about $200). Not only did the camera live up to my expectations, it surpassed them by leaps and bounds! Here are the things I have loved about this camera:

BATTERY - this camera has the best battery of any digital camera I have ever owned or used. …

EASY TO USE - I was able to …

PICTURE QUALITY - all of the pictures I've taken and printed out have been great. …

FEATURES - I love the ability to quickly and easily …

LCD SCREEN - I was hoping …

SD MEMORY CARD - I was also looking for a camera that used SD memory cards. Mostly because…

I cannot stress how highly I recommend this camera. I will never buy another digital camera besides Canon again. And the A610 (as well as the A620 - the 7.0MP version) is the best digital camera I've ever used.

Good Review:

The Sony DSC "P10" Digital Camera is the top pick for CSC. Running against cameras like Olympus stylus, Canon Powereshot, Sony V1, Nikon, Fuji, and More. The new release of 5.0 mega pixels has shot prices for digital cameras up to $1000+. This camera I purchased through a Private Dealer cost me $400.86. The Retail Price is Running $499.00 to $599.00. Purchase this camera from a wholesale dealer for the best price $377.00. Great Photo Even in dim light w/o a flash. The p10 is very compact. Can easily fit into any pocket. The camera can record 90 minutes of mpeg like a home movie. There are a lot of great digital cameras on the market that shoot good pictures and video. What makes the p10 the top pick is it comes with a rechargeable lithium battery. Many use AA batteries, the digital camera consumes theses AA batteries in about two hours time while the unit is on. That can add continuous expense to the camera. It's also the best resolution on the market. 6.0 megapix is out, though only a few. And the smallest that we found. Also the best price for a major brand.

Fair Review:

There is nothing wrong with the 2100 except for the very noticeable delay between pics. The camera's digital processor takes about 5 seconds after a photo is snapped to ready itself for the next one. Otherwise, the optics, the 3X optical zoom and the 2 megapixel resolution are fine for anything from Internet apps to 8" x 10" print enlarging. It is competent, not spectacular, but it gets the job done at an agreeable price point.

Bad Review:

I want to point out that you should never buy a generic battery, like the person from San Diego who reviewed the S410 on May 15, 2004, was recommending. Yes you'd save money, but there have been many reports of generic batteries exploding when charged for too long. And don't think if your generic battery explodes you can sue somebody and win millions. These batteries are made in sweatshops in China, India and Korea, and I doubt you can find anybody to sue. So play it safe, both for your own sake and the camera's sake. If you want a spare, get a real Canon one.

Figure 5. Example reviews

3.3 Annotation of Quality

According to the SPEC defined above, we built a ground-truth from the Amazon data set. We randomly selected 100 digital cameras and 50 reviews for each camera. Totally we have 4,909 reviews since some digital cameras have fewer than 50 unique reviews. Then we hired two annotators to label the reviews with the SPEC as their guideline. As the result, we have two independent copies of annotations on 4,909 reviews, with the labels of "best", "good", "fair", and "bad". Table 1 shows the confusion matrix between the two copies of annotation. The value of the *kappa* statistic (Cohen, 1960) calculated from the matrix is 0.8142. This shows that the two annotators achieved highly consistent results by following the SPEC, although they worked independently.

Annotation 1	Annotation 2				
	best	*good*	*fair*	*bad*	total
best	294	44	2	0	340
good	66	639	113	0	818
fair	0	200	1,472	113	1,785
bad	1	2	78	1,885	1,966
total	361	885	1,665	1,998	4,909

Table 1. Confusion matrix bet. the annotations

In order to examine the difference between our annotations and Amazon ground-truth, we evaluate the Amazon ground-truth against the annotations, with the measure of "error rate of preference pairs" (Herbrich et al, 1999).

$$ErrorRate = \frac{|incorrect\ preference\ pairs\ |}{|all\ preference\ pairs|} \quad (1)$$

where the "*preference pair*" is defined as a pair of reviews with a order. For example, a *best* review and a *good* review correspond to a preference pair with the order of "*best* review preferring to *good* review". The "*all preference pairs*" are collected from one of the annotations (the annotation 1 or the annotation 2) by ignoring the pairs from the same category. The "*incorrect preference pairs*" are the *preference pair*s collected from the Amazon ground-truth but not with the same order as that in the *all preference pairs*. The order of the *preference pair* collected from the Amazon ground-truth is evaluated on the basis of the *percentage* score as described in Section 3.1.

The error rate of preference pairs based on the annotation 1 and that based on the annotation 2 are 0.448 and 0.446, respectively, averaged over 100 digital cameras. The high error rate of preference pairs demonstrates that the Amazon ground-truth diverges from the annotations (our ground-truth) significantly.

To discover which kind of ground-truth is more reasonable, we ask an additional annotator (the third annotator) to compare these two kinds of ground-truth. More specifically, we randomly selected 100 preference pairs whose orders the two kinds of ground-truth don't agree on (called incorrect preference pairs in the evaluation above). As for our ground-truth, we choose the Annotation 1 in the new test. Then, the third annotator is asked to assign a preference order for each selected pair. Note that the third annotator is blind to both our specification and the existing preference order. Last, we evaluate the two kinds of ground-truth with the new annotation. Among 100 pairs, our ground-truth agrees to the new annotation on 85 pairs while the Amazon ground-truth agrees to the new annotation on 15 pairs. To confirm the result, yet another annotator (the fourth annotator) is called to repeat the same annotation independently as the third one. And we obtain the same statistical result (85 vs. 15) although the fourth annotator does not agree with the third annotator on some pairs.

In practice, we treat the reviews in the first three categories ("*best*", "*good*" and "*fair*") as high-quality reviews and those in the "*bad*" category as low-quality reviews, since our goal is to identify low quality reviews that should not be considered when creating product review summaries.

4 Classification of Product Reviews

We employ a statistical machine learning approach to address the problem of detecting low-quality products reviews.

Given a training data set $D = \{x_i, y_i\}_1^n$, we construct a model that can minimize the error in prediction of y given x (generalization error). Here $x_i \in X$ and $y_i = \{high\ quality\ , low\ quality\}$ represents a product review and a label, respectively. When applied to a new instance *x*, the model predicts the corresponding *y* and outputs the score of the prediction.

4.1 The Learning Model

In our study, we focus on differentiating low-quality product reviews from high-quality ones. Thus, we treat the task as a binary classification problem.

We employ SVM (Support Vector Machines) (Vapnik, 1995) as the model of classification. Given an instance *x* (product review), SVM assigns a score to it based on

$$f(x) = w^T x + b \quad (2)$$

where *w* denotes a vector of weights and *b* denotes an intercept. The higher the value of *f(x)* is, the higher the quality of the instance *x* is. In classification, the sign of *f(x)* is used. If it is positive, then *x* is classified into the positive category (high-quality reviews), otherwise into the negative category (low-quality reviews).

The construction of SVM needs labeled training data (in our case, the categories are "high-quality reviews" and "low-quality reviews"). Briefly, the learning algorithm creates the "hyper plane" in (2), such that the hyper plane separates the positive and negative instances in the training data with the largest "margin".

4.2 Product Feature Resolution

Product features (e.g., "image quality" for digital camera) in a review are good indicators of review quality. However, different product features may refer to the same meaning (e.g., "*battery life*" and "*power*"), which will bring redundancy in the study. In this paper, we formulize the problem as the "resolution of product features". Thus, the problem is reduced to how to determine the equivalence of a product feature in different forms.

In (Hu and Liu, 2004), the matching of different product features is mentioned briefly and addressed by fuzzy matching. However, there exist many cases where the method fails to match the multiple mentions, e.g., "*battery life*" and "*power*", because it only considers string similarity. In this paper we propose to resolve the problem by leveraging two kinds of evidence: one is "surface string" evidence, the other is "contextual evidence".

We use *edit distance* (Ukkonen, 1985) to compare the similarity between the surface strings of two mentions, and use *contextual similarity* to reflect the semantic similarity between two mentions.

When using contextual similarity, we split all the reviews into sentences. For each mention of a product feature, we take it as a query and search for all the relevant sentences. Then we construct a vector for the mention, by taking each unique term in the relevant sentences as a dimension of the vector. The cosine similarity between two vectors of mentions is then present to measure the contextual similarity between two mentions.

4.3 Feature Development for Learning

To detect low-quality reviews, our proposed approach explores three aspects of product reviews, namely informativeness, subjectiveness, and readability. We denote the features employed for learning as "learning features", discriminative from the "product features" we discussed above.

4.3.1 Features on Informativeness

As for informativeness, the resolution of product features is employed when we generate the learning features as listed below. Pairs mapping to the same product feature will be treated as the same product feature, when we calculate the frequency and the number of product features. We apply the approach proposed in (Hu and Liu, 2004) to extract product features.

We also use a list of product names and a list of brand names to generate the learning features. Both lists can be collected from the Amazon site because they are relatively stable within a time interval.

The learning features on the informativeness of a review are as follows.

➢ **Sentence level (SL)**

- The number of sentences in the review
- The average length of sentences
- The number of sentences with product features

➢ **Word level (WL)**

- The number of words in the review
- The number of products (e.g., DMC-FZ50, EX-Z1000) in the review
- The number of products in the title of a review
- The number of brand names (e.g., Canon, Sony) in the review
- The number of brand names in the title of a review

➢ **Product feature level (PFL)**

- The number of product features in the review
- The total frequency of product features in the review
- The average frequency of product features in the review
- The number of product features in the title of a review
- The total frequency of product features in the title of a review

4.3.2 Features on Readability

We make use of several features at paragraph level which indicate the underlying structure of the reviews. These features include,

- The number of paragraphs in the review
- The average length of paragraphs in the review
- The number of paragraph separators in the review

Here, we refer to the keywords, such as "Pros" vs. "Cons" as "paragraph separators". The keywords usually appear at the beginning of paragraphs for categorizing two contrasting aspects of a product. We extract the nouns and noun phrases at the beginning of each paragraph from the 4,909 reviews and use the most frequent 30 pairs of keywords as paragraph separators. Table 2 provides some examples of the extracted separators.

Separators		***Separators***	
Positive	***Negative***	***Positive***	***Negative***
Pros	Cons	The Good	The Bad
Strength	Weakness	Thumb up	Bummer
PLUSES	MINUSES	Positive	Negative
Advantages	Drawbacks	Likes	Dislikes
The upsides	Downsides	GOOD THINGS	BAD THINGS

Table 2. Examples of paragraph separators

4.3.3 Features on Subjectiveness

We also take the subjectiveness of reviews into consideration. Unlike previous work (Kim et al, 2006; Zhang and Varadarajan, 2006) using shallow syntactic information directly, we use a sentiment analysis tool (Hu and Liu, 2004) which aggregates a set of shallow syntactic information. The tool is a classifier capable of determining the sentiment polarity of each sentence. We create three learning features regarding the subjectiveness of reviews.

- The percentage of positive sentences in the review
- The percentage of negative sentences in the review
- The percentage of subjective sentences (regardless of positive or negative) in the review

5 Experiments

In this section, we describe our experiments with the proposed classification-based approach to low-quality review detection, and its effectiveness on the task of opinion summarization.

5.1 Detecting Low-quality Reviews

In our proposed approach, the problem of assessing quality of reviews is formalized as a binary classification problem. We conduct experiments by taking reviews in the categories of “best”, “good”, and “fair” as high-quality reviews and those in the “bad” category as low-quality reviews.

As for classification model, we utilize the SVMLight toolkit (Joachims, 2004). We randomly divide the 100 queries of digital cameras into two sets, namely a training set of 50 queries and a test set of 50 queries. For the two copies of annotations, we use the same division. We use the training set from “annotation 1” to train the model and apply the model to the test sets from both “annotation 1” and “annotation 2”, respectively. Table 3 reports the accuracies of our approach to review classification. The accuracy is defined as the percentage of correctly classified reviews.

We take the approach that utilizes only the category of features on sentence level (SL) as the baseline, and incrementally add other categories of features on informativeness, readability and subjectiveness. We can see that both the features on word level (WL) and those on product feature level (PFL) can improve the performance of classification much. The features on readability can still increase the accuracy although the contribution is much less. The features on subjectiveness, however, make no contribution.

Feature Category		Annotation1	Annotation2
Informative-ness	SL	73.59%	72.81%
	WL	80.41%	79.15%
	PFL	83.30%	82.37%
Readability		83.93%	82.91%
Subjectiveness		83.84%	82.96%

Table 3. Low-quality reviews detection

We also conduct a more detailed analysis on each individual feature. Two categories of features on “title” and “brand name” have poor performance, which is due to the lack of information in the title and the low coverage of brand names in a review, respectively.

5.2 Summarizing Sentiments of Reviews

One potential application of low-quality review detection is the opinion summarization of reviews.

The process of opinion summarization of reviews with regards to a query of a product consists of the following steps (Liu et al, 2005):

1. From each of the reviews, identify every text segment with opinion in the review, and determine the polarities of the opinion segments.
2. For each product feature, generate a positive opinion set and a negative opinion set of opinion segments, denoted as $\mathrm{POS}(f)$ and $\mathrm{NOS}(f)$.
3. For each product feature, aggregate the numbers of segments in $\mathrm{POS}(f)$ and$\mathrm{NOS}(f)$, as opinion summarization on the product feature.

In this process, all the reviews contribute the same. However, different reviews do hold different authorities. A positive/negative opinion from a high-quality review should not have the same weight as that from a low-quality review.

We use a two-stage approach to enhance the reliability of summarization. That is, we add a process of low-quality review detection before the summarization process, so that the summarization result is obtained based on the high-quality reviews only. We are to demonstrate how much difference the proposed two-stage approach can bring into the opinion summarization.

We use the best classification model trained as described in Section 5.1 to filter low-quality reviews, and do summarization on the high-quality reviews associated to the 50 test queries. We denote the proposed approach and the old approach as "two-stage" and "one-stage", respectively. Due to the limited space, we only give a visual comparison of the two approaches on "image quality" in Figure 6. The upper figure shows the summarization of positive opinions and the lower figure shows that of negative opinions. From the figures we can see that the two-stage approach preserves fewer text segments as the result of filtering out many low-quality product reviews.

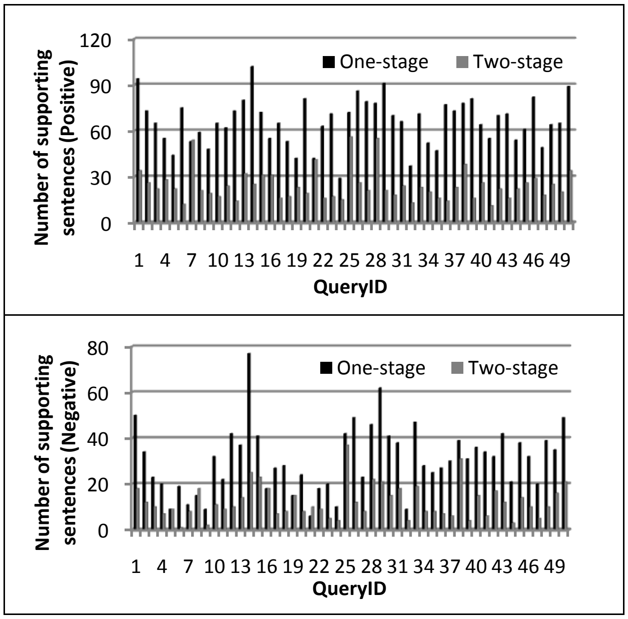

Figure 6. Summarization on "image quality"

To show the comparison on more features in a compressed space, we give the statistic ratio of change between two approaches instead. As for the evaluation measure, we define "*RatioOfChange*" (*ROC)* on a feature *f* as,

$$\mathrm{ROC}(f) = \frac{\mathrm{Rate}_{\mathrm{one-stage}}\,(f) - \mathrm{Rate}_{\mathrm{two-stage}}\,(f)}{\mathrm{Rate}_{\mathrm{one-stage}}\,(f)} \qquad (3)$$

where Rate $_{*}(f)$ is defined as,

$$\mathrm{Rate}_{*}(f) = \frac{|\mathrm{POS}(f)|}{|\mathrm{POS}(f)| + |\mathrm{NOS}(f)|} \qquad (4)$$

Table 4 shows some statistic results on *ROC* on five product features, namely "image quality"(IQ), "battery", "LCD screen" (LCD), "flash" and "movie mode" (MM). The values in the cells are the percentage of queries whose *ROC* is larger/smaller than the respective thresholds. We can see that a large portion of queries have big changes on the values of *ROC*. This means that the result achieved by the two-stage approach is substantially different from that achieved by the one-stage approach.

%Query	***RatioOfChange* (+)**					
	>0.30	**>0.25**	**>0.20**	**>0.15**	**>0.10**	**>0.05**
IQ	2%	4%	4%	10%	14%	22%
Battery	10%	14%	18%	30%	38%	50%
LCD	12%	18%	20%	22%	24%	28%
Flash	6%	10%	16%	20%	26%	42%
MM	6%	8%	8%	12%	18%	26%
%Query	***RatioOfChange* (-)**					
	<-0.30	**<-0.25**	**<-0.20**	**<-0.15**	**<-0.10**	**<-0.05**
IQ	4%	6%	10%	14%	18%	44%
Battery	2%	4%	4%	10%	14%	22%
LCD	4%	4%	8%	12%	22%	28%
Flash	4%	6%	8%	16%	18%	28%
MM	8%	10%	16%	18%	34%	42%

Table 4. *RatioOfChange* on five features

There is no standard way to evaluate the quality of opinion summarization as it is rather a subjective problem. In order to demonstrate the impact of the two-stage approach, we turn to external authoritative sources other than Amazon.com as the objective evaluation reference. We observe that CNET[2] provides a professional "*editor's review*" for many products, which gives a rating in the range of 1~10 on product features. 9 digital cameras out of the 50 test queries are found to have the editor's rating on "image quality" at CNET. We use this rating to compare with the results of our opinion summarization. We rescale the *Rate* scores obtained by both the one-stage approach and the two-stage approach into the range of 1-10 in order to perform the comparison.

Figure 7 provides the visual comparison. We can see that the result achieved by the two-stage approach has a much better (closer) resemblance to CNET rating than one-stage approach does. This indicates that our two-stage approach can achieve a more consistent summarization result to the professional evaluations by the editors. Although the CNET rating is not the absolute standard for product evaluation, it provides a professional yet objective evaluation of the products. Therefore, the experimental results demonstrate that our proposed approach could achieve more reliable opinion summarization which is closer to the generic evaluation from authoritative sources.

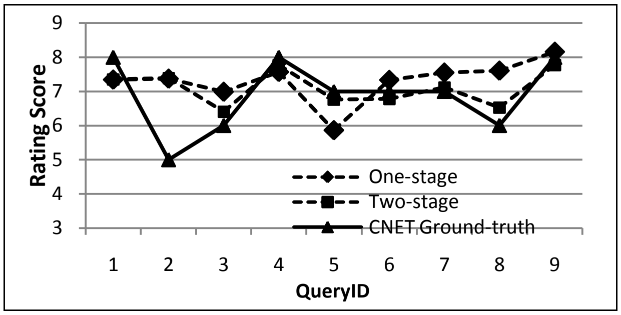

Figure 7. Comparison with CNET rating

6 Conclusion

In this paper, we studied the problem of detecting low-quality product reviews. Our contribution can be summarized in two-fold: (1) we discovered **three types of biases** in the ground-truth used extensively in the existing work, and proposed a specification on the quality of product reviews. The three biases that we discovered are *imbalance vote bias*, *winner circle bias*, and *early bird bias*. (2) Rooting on the new ground-truth (conforming to the proposed specification), we proposed a classification-based approach to low-quality product review detection, which yields better performance of **opinion summarization**.

We hope to explore our future work in several areas, such as further consolidating the new ground-truth from different points of view and verifying the effectiveness of low-quality review detection with other applications.

Abstract

Parallel corpus is an indispensable resource for translation model training in statistical machine translation (SMT). Instead of collecting more and more parallel training corpora, this paper aims to improve SMT performance by exploiting full potential of the existing parallel corpora. Two kinds of methods are proposed: offline data optimization and online model optimization. The offline method adapts the training data by redistributing the weight of each training sentence pairs. The online method adapts the translation model by redistributing the weight of each predefined submodels. Information retrieval model is used for the weighting scheme in both methods. Experimental results show that without using any additional resource, both methods can improve SMT performance significantly.

1 Introduction

Statistical machine translation relies heavily on the available training data. Typically, the more data is used to estimate the parameters of the translation model, the better it can approximate the true translation probabilities, which will obviously lead to a higher translation performance. However, large corpora are not easily available. The collected corpora are usually from very different areas. For example, the parallel corpora provided by LDC come from quite different domains, such as Hongkong laws, Hangkong Hansards and Hongkong news. This results in the problem that a translation system trained on data from a particular domain(e.g. Hongkong Hansards) will perform poorly when translating text from a different domain(e.g. news articles). Our experiments also show that simply putting all these domain specific corpora together will not always improve translation quality. From another aspect, larger amount of training data also requires larger computational resources. With the increasing of training data, the improvement of translation quality will become smaller and smaller. Therefore, while keeping collecting more and more parallel corpora, it is also important to seek effective ways of making better use of available parallel training data.

There are two cases when we train a SMT system. In one case, we know the target test set or target test domain, for example, when building a specific domain SMT system or when participating the NIST MT evaluation[1]. In the other case, we are unaware of any information of the testing data. This paper presents two methods to exploit full potential of the available parallel corpora in the two cases. For the first case, we try to optimize the training data offline to make it match the test data better in domain, topic and style, thus improving the translation performance. For the second case, we first divide the training data into several domains and train submodels for each domain. Then, in the translation process, we try to optimize the predefined models according to the online input source sentence. Information retrieval model is used for similar sentences retrieval in both methods. Our preliminary experiments show that both methods can improve SMT performance without using any additional data.

The remainder of this paper is organized as follows: Section 2 describes the offline data selection and optimization method. Section 3 describes the online model optimization method. The evaluation and discussion are given in section 4. Related work is introduced before concluding.

2 Offline training data optimization

In offline training data optimization, we assume that the target test data or target test domain is known before building the translation model. We first select sentences similar to the test text using information retrieval method to construct a small and adapted training data. Then the extracted similar subset is used to optimize the distribution of the whole training data. The adapted and the optimized training data will be used to train new translation models.

2.1 Similar data selection using TF-IDF

We use information retrieval method for similar data retrieval. The standard TF-IDF (Term Frequency and Inverse Document Frequency) term weighting scheme is used to measure the similarity between the test sentence and the training sentence.

TF-IDF is a similarity measure widely used in information retrieval. Each document D_i is represented as a vector $(w_{i1}, w_{i2}, ..., w_{in})$, n is the size of the vocabulary. w_{ij} is calculate as follows:

$$w_{ij} = tf_{ij} \times \log(idf_j)$$

where,

tf_{ij} is the term frequency(TF) of the *j*-th word in the vocabulary in the document D_i, i.e. the number of occurrences;

idf_j is the inverse document frequency(IDF) of the *j*-th word calculated as below:

$$idf_j = \frac{\#documents}{\#documents\ containing\ \text{j - th term}}.$$

The similarity between two documents is then defined as the cosine of the angle between the two vectors.

We perform information retrieval using the Lemur toolkit[2]. The source language part of the parallel training data is used as the document collection. Each sentence represents one document. Each sentence from the test data or test domain is used as one separate query. In the sentence retrieval process, both the query and the document are converted into vectors by assigning a term weight to each word. Then the cosine similarity is calculated proportional to the inner product of the two vectors. All retrieved sentences are ranked according to their similarity with the query. We pair each of the retrieved sentences with the corresponding target part and the top N most similar sentences pairs are put together to form an adapted parallel data. N ranges from one to several thousand in our experiments. Since Lemur toolkit gives the similarity score for each retrieved sentences, it is also possible to select the most similar sentences according to the similarity score.

Note that the selected similar data can contain duplicate sentences as the top N retrieval results for different test sentences can contain the same training sentences. The duplicate sentences will force the translation probability towards the more often seen words. Intuitively, this could help. In experiment section, we will compare experimental results by keeping or removing duplicates to see how the duplicate sentences affect the translations.

The selected subset contains the similar sentences with the test data or test domain. It matches the test data better in domain, topic and style. Hopefully, training translation model using this adapted parallel data may helpful for improving translation performance. In addition, the translation model trained using the selected subset is usually much smaller than that trained using the whole translation data. Limiting the size of translation model is very important for some real applications. Since SMT systems usually require large computation resource. The complexity of standard training and decoding algorithm depends mainly on the size of the parallel training data and the size of the translation model. Limiting the size of the training data with the similar translation performance would also reduce the memories and speed up the translations.

In the information retrieval process, we only use the source language part for document indexing and query generating. It is easy to get source part of the test data. This is different from the common language model adaptation methods, which have to do at lease one pass machine translation to get the candidate English translation as query(Zhao 2004, Zhang 2006). So our method has the advantage that it is independent from the quality of baseline translation system.

[2] http://www.cs.cmu.edu/~lemur/

2.2 Training data optimization

There are two factors on training data that influence the translation performance of SMT system: the scale and the quality. In some sense, we improve the quality of the training data by selecting the similar sentence to form an adapted training set. However, we also reduce the scale of the training data at the same time. Although this is helpful for some small device applications, it is also possible to induce the data sparseness problem. Here, we introduce a method to optimize between the scale and the quality of the training data.

The basic idea is that we still use all the available training data; by redistributing the weight of each sentence pairs we adapt the whole training data to the test domain. In our experiments, we simply combine the selected small similar subset and the whole training data. The weights of each sentence pairs are changed accordingly. Figure 1 shows the procedure of the optimization.

1	...	...

Figure 1. Training data optimization

As can be seen, through the optimization, the weight of the similar sentence pairs are increased, while the general sentence pairs still have an ordinary weight. This make the translation model inclined to give higher probabilities to the adapted words, and at the same time avoid the data sparseness problem. Since we only change the weight of the sentence pairs, and no new training data is introduced, the translation model size trained on the optimized data will keep as the same as the original one. We use GIZA++ toolkit[3] for word alignment training in the training process. The input training file formats for GIZA++ is as follows: Each training sentence pair is stored in three lines. The first line is the number of times this sentence pair occurred. The second line is the source sentence where each token is replaced by its unique integer id and the third is the target sentence in the same format. To deal with our optimized training data, we only need to change the number of sentence pairs in the first line accordingly. This will not call for extra training time and memory for the whole training process.

It might be beneficial to investigate other sophisticated weighting schemes under the similar idea, such as to give more precise fractional weights to the sentences according the retrieval similarity scores.

3 Online model optimization

In most circumstances, we don't know exactly the test data or the test domain when we train a machine translation system. This results in the fact that the performance of the translation system highly depends on the training data and the test data it is used in. To alleviate this blindfold status and maximize the potential of the available training corpora, we propose a novel online model optimization method.

The basic idea is that: several candidate translation models are prepared in training stage. In particularly, a general model is also prepared. Then, in the translation process, the similarity between the input sentence and the predefined models is calculated online to get the weights of each model. The optimized model is used to translate the input sentence.

There are two problems in the method: how to prepare submodels in training process and how to optimize the model weight online in translation process.

3.1 Prepare the submodels

There are several ways to prepare submodels in training process. If the training data comes from very different sources, we can divide the data according to its origins. Otherwise, we can use clustering method to separate the training corpus into several classes. In addition, our offline data adaptation method can also be used for submodel preparation. For each candidate domain, we can use the

[3] http://www.fjoch.com/GIZA++.html

source side of a small corpus as queries to extract a domain specific training set. In this case, a sentence pair in the training data may occur in several sub training data, but this doesn't matter. The general model is used when the online input is not similar to any prepared submodels. We can use all available training data to train the general model since generally larger data can get better model even there are some noises.

3.2 Online model weighting

We also use TF-IDF information retrieval method for online model weighting. The procedure is as follows:

For each input sentence:

1. *Do IR on training data collection, using the input sentence as query.*
2. *Determine the weights of submodels according to the retrieved sentences.*
3. *Use the optimized model to translate the sentence.*

The information retrieval process is the same as the offline data selection except that each retrieved sentence is attached with the sub-corpus information, i.e. it belongs to which sub-models in the training process.

With the sub-corpus information, we can calculate the weights of submodels. We get the top N most similar sentences, and then calculate proportions of each submodel's sentences. The proportion can be calculated use the count of the sentences or the similarity score of the sentences. The weight of each submodel can be determined according to the proportions.

Our optimized model is the log linear interpolation of the sub-models as follows:

$$\hat{p}(e \mid c) = p_0(e \mid c)^{\delta_0} \times \prod_{i=1}^{M} p_i(e \mid c)^{\delta_i}$$

$$\hat{e} = \arg\max_{e}(\delta_0 \log(p_0(e \mid c)) + \sum_{i=1}^{M} \delta_i \log(p_i(e \mid c)))$$

where, p_0 is the probability of general model, p_i is the probability of submodel *i*. δ_0 is the weight of general model. δ_i is the weight of submodel *i*. Each model *i* is also implemented using log linear model in our SMT system. So after the log operation, the submodels are interpolated linearly.

In our experiments, the interpolation factor δ_i is determined using the following four simple weighting schemes:

Weighting scheme 1:

$$\delta_0 = 0; \quad \delta_{max\_model} = 1; \quad \delta_{i \neq max\_model} = 0;$$

Weighting scheme 2:

```
if Proportion(max_model) > 0.5
    Use weighting scheme1;
else
    $\delta_0 = 1$;  $\delta_i = 0$;
```

Weighting scheme 3:

$$\delta_0 = 0;$$

$$\delta_i = \text{Proportion } (model_i);$$

Weighting scheme 4:

```
if Proportion(max_model) > 0.5
    Use weighting scheme3;
else
    $\delta_0 = 0.5$;
    $\delta_i = 0.5 \times$ Proportion $(model_i)$;
```

where, *model*i is the *i*-th submodel, $i = (1...M)$. Proportion (*model*$_i$) is the proportion of *model*$_i$ in the retrieved results. We use count for proportion calculation. *max_model* is the submodel with the max proportion score.

The training and translation procedure of online model optimization is illustrated in Figure 2.

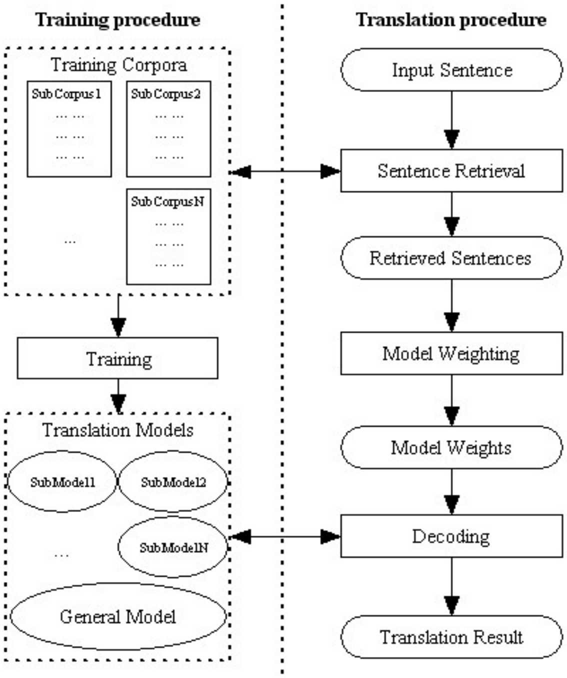

Figure 2. Online model optimization

The online model optimization method makes it possible to select suitable models for each individual test sentence. Since the IR process is done on a fixed training data, the size of the index data is quite small compared with the web IR. The IR process will not take much time in the translation.

4 Experiments and evaluation

4.1 Experimental setting

We conduct our experiments on Chinese-to-English translation tasks. The baseline system is a variant of the phrase-base SMT system, implemented using log-linear translation model (He et al. 2006). The baseline SMT system is used in all experiments. The only difference between them is that they are trained on different parallel training data.

In training process, we use GIZA++[4] toolkit for word alignment in both translation directions, and apply "grow-diag-final" method to refine it (Koehn et al., 2003). We change the preprocess part of GIZA++ toolkit to make it accept the weighted training data. Then we use the same criterion as suggested in (Zens et al., 2002) to do phrase extraction. For the log-linear model training, we take minimum-error-rate training method as described in (Och, 2003). The language model is trained using Xinhua portion of Gigaword with about 190M words. SRI Language Modeling toolkit[5] is used to train a 4-gram model with modified Kneser-Ney smoothing(Chen and Goodman, 1998). All experiments use the same language model. This ensures that any differences in performance are caused only by differences in the parallel training data.

Our training data are from three LDC corpora as shown in Table 1. We random select 200,000 sentence pairs from each corpus and combine them together as the baseline corpus, which includes 16M Chinese words and 19M English words in total. This is the usual case when we train a SMT system, i.e. we simply combine all corpora from different origins to get a larger training corpus.

We use the 2002 NIST MT evaluation test data as our development set, and the 2005 NIST MT test data as the test set in offline data optimization experiments. In both data, each sentence has four human translations as references. The translation quality is evaluated by BLEU metric (Papineni et al., 2002), as calculated by mteval-v11b.pl[6] with case-sensitive matching of n-grams.

Corpus	LDC No.	Description	# sent. pairs
FBIS	LDC2003E14	FBIS Multilanguage Texts	200000
HK_Hansards	LDC2004T08	Hong Kong Hansards Text	200000
HK_News	LDC2004T08	Hong Kong News Text	200000
Baseline	-	All above data	600000

Table 1. Training corpora

4.2 Baseline experiments

We first train translation models on each sub training corpus and the baseline corpus. The development set is used to tune the feature weights. The results on test set are shown in Table 2.

System	BLEU on dev set	BLEU on test set
FBIS	0.2614	0.2331
HK_Hansards	0.1679	0.1624
HK_News	0.1748	0.1608
Baseline	0.2565	0.2363

Table 2. Baseline results

From the results we can see that although the size of each sub training corpus is similar, the translation results from the corresponding system are quite different on the same test set. It seems that the FBIS corpus is much similar to the test set than the other two corpora. In fact, it is the case. The FBIS contains text mainly from China mainland news stories, while the 2005 NIST test set also include lots of China news text. The results illustrate the importance of selecting suitable training data.

When combining all the sub corpora together, the baseline system gets a little better result than the sub systems. This indicates that larger data is useful even it includes some noise data. However, compared with the FBIS corpus, the baseline corpus contains three times larger data, while the improvement of translation result is not significant. This indicates that simply putting different corpora together is not a good way to make use of the available corpora.

[6] http://www.nist.gov/speech/tests/mt/resources/scoring.htm

4.3 Offline data optimization experiments

We use baseline corpus as initial training corpus, and take Lemur toolkit to build document index on Chinese part of the corpus. The Chinese sentences in development set and test set are used as queries. For each query, N = 100, 200, 500, 1000, 2000 similar sentences are retrieved from the indexed collection. The extracted similar sentence pairs are used to train the new adapted translation models. Table 3 illustrates the results. We give the distinct pair numbers for each adapted set and compare the size of the translation models. To illustrate the effect of duplicate sentences, we also give the results with duplicates and without duplicates (distinct).

System	Distinct pairs	Size of trans model	BLEU on duplicates	BLEU on distinct
Baseline	600000	2.41G	0.2363	0.2363
Top100	91804	0.43G	0.2306	0.2346
Top200	150619	0.73G	0.2360	0.2345
Top500	261003	1.28G	0.2415	0.2370
Top1000	357337	1.74G	0.2463	0.2376
Top2000	445890	2.11G	0.2351	0.2346

Table 3. Offline data adaptation results

The results show that:

1. By using similar data selection, it is possible to use much smaller training data to get comparable or even better results than the baseline system. When N=200, using only 1/4 of the training data and 1/3 of the model size, the adapted translation model achieves comparable result with the baseline model. When N=500, the adapted model outperforms the baseline model with much less training data. The results indicate that relevant data is better data. The method is particular useful for SMT applications on small device.

2. In general, using duplicate data achieves better results than using distinct data. This justifies our idea that give a higher weight to more similar data will benefit.

3. With the increase of training data size, the translation performance tends to improve also. However, when the size of corpus achieves a certain scale, the performance may drop. This maybe because that with the increase of the data, noisy data may also be included. More and more included noises may destroy the data. It is necessary to use a development set to determine an optimal size of N.

We combine each adapted data with the baseline corpus to get the optimized models. The results are shown in Table 4. We also compare the adapted models (TopN) and the optimized models (TopN+) in the table.

Without using any additional data, the optimized models achieve significant better results than the baseline model by redistributing the weight of training sentences. The optimized models also outperform adapted models when the size of the adapted data is small since they make use of all the available data which decrease the influence of data sparseness. However, with the increase of the adapted data, the performance of optimized models is similar to that of the adapted models.

System	Distinct pairs	BLEU on TopN	BLEU on TopN+
Baseline	600000	0.2363	0.2363
Top100+	600000	0.2306	0.2387
Top200+	600000	0.2360	0.2443
Top500+	600000	0.2415	0.2461
Top1000+	600000	0.2463	0.2431
Top2000+	600000	0.2351	0.2355

Table 4. Offline data optimization results

4.4 Online model optimization experiments

Since 2005 NIST MT test data tends bias to FBIS corpus too much, we build a new test set to evaluate the online model optimization method. We randomly select 500 sentences from extra part of FBIS, HK_Hansards and HK_News corpus respectively (i.e the selected 1500 test sentences are not included in any of the training set). The corresponding English part is used as translation reference. Note that there is only one reference for each test sentence. We also include top 500 sentence and their first reference translation of 2005 NIST MT test data in the new test set. So in total, the new test contains 2000 test sentences with one translation reference for each sentence. The test set is used to simulate SMT system's online inputs which may come from various domains.

The baseline translation results are shown in Table 5. We also give results on each sub test set (denotes as Xcorpus_part). Please note that the absolute BLEU scores are not comparable to the previous experiments since there is only one reference in this test set.

As expected, using the same domain data for training and testing achieves the best results as indicate by **bold fonts**. The results demonstrate again that relevant data is better data.

To test our online model optimization method, we divide the baseline corpus according to the origins of sub corpus. That is, the FBIS, HK_ Hansards and HK_News models are used as three sub-models and the baseline model is used as general model. The four weighting schemes described in section 3.2 are used as online weighting schemes individually. The experimental results are shown in Table 6. S_*i* indicates the system using weighting scheme *i*.

System **Test data**	**FBIS**	**HK_ Hansards**	**HK_ News**	**Baseline**
FBIS-part	**0.1096**	0.0687	0.0622	0.1030
HK_Hans_part	0.0726	**0.0918**	0.0846	0.0897
HK_News_part	0.0664	0.0801	**0.0936**	0.0870
MT05_part	0.1130	0.0805	0.0776	0.1116
Whole test set	0.0937	0.0799	0.0781	0.0993

Table 5. Baseline results on new test set

System **Test data**	**S_1**	**S_2**	**S_3**	**S_4**
FBIS-part	0.1090	0.1090	0.1089	0.1089
HK_Hans_part	0.0906	0.0903	0.0902	0.0902
HK_News_part	0.0952	0.0950	0.0933	0.0934
MT05_part	0.1119	0.1123	0.1149	0.1151
Whole test set	0.1034	0.1034	0.1038	0.1038

Table 6. Online model optimization results

Different weighting schemes don't show significant improvements from each other. However, all the four weighting schemes achieve better results than the baseline system. The improvements are shown not only on the whole test set but also on each part of the sub test set. The results justify the effectiveness of our online model optimization method.

5 Related work

Most previous research on SMT training data is focused on parallel data collection. Some work tries to acquire parallel sentences from web (Nie et al. 1999; Resnik and Smith 2003; Chen et al. 2004). Others extract parallel sentences from comparable or non-parallel corpora (Munteanu and Marcu 2005, 2006). These work aims to collect more parallel training corpora, while our work aims to make better use of existing parallel corpora.

Some research has been conducted on parallel data selection and adaptation. Eck et al. (2005) propose a method to select more informative sentences based on n-gram coverage. They use n-grams to estimate the importance of a sentence. The more previously unseen n-grams in the sentence the more important the sentence is. TF-IDF weighting scheme is also tried in their method, but didn't show improvements over n-grams. This method is independent of test data. Their goal is to decrease the amount of training data to make SMT system adaptable to small devices. Similar to our work, Hildebrand et al. (2005) also use information retrieval method for translation model adaptation. They select sentences similar to the test set from available in-of-domain and out-of-domain training data to form an adapted translation model. Different from their work, our method further use the small adapted data to optimize the distribution of the whole training data. It takes the full advantage of larger data and adapted data. In addition, we also propose an online translation model optimization method, which make it possible to select adapted translation model for each individual sentence.

Since large scale monolingual corpora are easier to obtain than parallel corpora. There has some research on language model adaptation recent years. Zhao et al. (2004) and Eck et al.(2004) introduce information retrieval method for language model adaptation. Zhang et al.(2006) and Mauser et al.(2006) use adapted language model for SMT re-ranking. Since language model is built for target language in SMT, one pass translation is usually needed to generate n-best translation candidates in language model adaptation. Translation model adaptation doesn't need a pre-translation procedure. Comparatively, it is more direct. Language model adaptation and translation model adaptation are good complement to each other. It is possible that combine these two adaptation approaches could further improve machine translation performance.

6 Conclusion and future work

This paper presents two new methods to improve statistical machine translation performance by making better use of the available parallel training corpora. The offline data selection method adapts the training corpora to the test domain by retrieving similar sentence pairs and redistributing their weight in the training data. Experimental results show that the selected small subset achieves comparable or even better performance than the baseline system with much less training data. The optimized training data can further improve translation performance without using any additional resource. The online model optimization method adapts the translation model to the online test sentence by redistributing the weight of each predefined submodels. Preliminary results show the effectiveness of the method. Our work also demonstrates that in addition to larger training data, more relevant training data is also important for SMT model training.

In future work, we will improve our methods in several aspects. Currently, the similar sentence retrieval model and the weighting schemes are very simple. It might work better by trying other sophisticated similarity measure models or using some optimization algorithms to determine submodel's weights. Introducing language model optimization into our system might further improve translation performance.

Abstract

We present a domain-independent unsupervised topic segmentation approach based on hybrid document indexing. Lexical chains have been successfully employed to evaluate lexical cohesion of text segments and to predict topic boundaries. Our approach is based in the notion of semantic cohesion. It uses spectral embedding to estimate semantic association between content nouns over a span of multiple text segments. Our method significantly outperforms the baseline on the topic segmentation task and achieves performance comparable to state-of-the-art methods that incorporate domain specific information.

1 Introduction

The goal of topic segmentation is to discover story boundaries in the stream of text or audio recordings. Story is broadly defined as segment of text containing topically related sentences. In particular, the task may require segmenting a stream of broadcast news, addressed by the Topic Detection and Tracking (TDT) evaluation project (Wayne, 2000; Allan, 2002). In this case topically related sentences belong to the same news story. While we are considering TDT data sets in this paper, we would like to pose the problem more broadly and consider a domain-independent approach to topic segmentation.

Previous research on topic segmentation has shown that lexical coherence is a reliable indicator of topical relatedness. Therefore, many approaches have concentrated on different ways of estimating lexical coherence of text segments, such as semantic similarity between words (Kozima, 1993), similarity between blocks of text (Hearst, 1994), and adaptive language models (Beeferman et al., 1999). These approaches use word repetitions to evaluate coherence. Since the sentences covering the same story represent a coherent discourse segment, they typically contain the same or related words. Repeated words build lexical chains that are consequently used to estimate lexical coherence. This can be done either by analyzing the number of overlapping lexical chains (Hearst, 1994) or by building a short-range and long-range language model (Beeferman et al., 1999). More recently, topic segmentation with lexical chains has been successfully applied to segmentation of news stories, multi-party conversation and audio recordings (Galley et al., 2003).

When the task is to segment long streams of text containing stories which may continue at a later point in time, for example developing news stories, building of lexical chains becomes intricate. In addition, the word repetitions do not account for synonymy and semantic relatedness between words and therefore may not be able to discover coherence of segments with little word overlap.

Our approach aims at discovering semantic relatedness beyond word repetition. It is based on the notion of semantic cohesion rather than lexical cohesion. We propose to use a similarity metric between segments of text that takes into account semantic associations between words spanning a number of segments. This method approximates lexical chains by averaging the similarity to a number of previous text

Proceedings of the 2007 Joint Conference on Empirical Methods in Natural Language Processing and Computational Natural Language Learning, pp. 351–359, Prague, June 2007. ©2007 Association for Computational Linguistics

segments and accounts for synonymy by using a hybrid document indexing scheme. Our text segmentation experiments show a significant performance improvement over the baseline.

The rest of the paper is organized as follows. Section 2 discusses hybrid indexing. Section 3 describes our segmentation algorithm. Section 5 reports the experimental results. We conclude in section 6.

2 Hybrid Document Indexing

For the topic segmentation task we would like to define a similarity measure that accounts for synonymy and semantic association between words. This similarity measure will be used to evaluate semantic cohesion between text units and the decrease in semantic cohesion will be used as an indicator of a story boundary. First, we develop a document representation which supports this similarity measure.

Capturing semantic relations between words in a document representation is difficult. Different approaches tried to overcome the term independence assumption of the bag-of-words representation (Salton and McGill, 1983) by using distributional term clusters (Slonim and Tishby, 2000) and expanding the document vectors with synonyms, see (Levow et al., 2005). Since content words can be combined into semantic classes there has been a considerable interest in low-dimensional representations. Latent Semantic Analysis (LSA) (Deerwester et al., 1990) is one of the best known dimensionality reduction algorithms. In the LSA space documents are indexed with latent semantic concepts. LSA maps all words to low dimensional vectors. However, the notion of semantic relatedness is defined differently for subsets of the vocabulary. In addition, the numerical information, abbreviations and the documents' style may be very good indicators of their topic. However, this information is no longer available after the dimensionality reduction.

We use a hybrid approach to document indexing to address these issues. We keep the notion of latent semantic concepts and also try to preserve the specifics of the document collection. Therefore, we divide the vocabulary into two sets: nouns and the rest of the vocabulary. The set of nouns does not include proper nouns. We use a method of spectral embedding, as described below and compute a low-dimensional representation for documents using only the nouns. We also compute a *tf-idf* representation for documents using the other set of words. Since we can treat each latent semantic concept in the low-dimensional representation as part of the vocabulary, we combine the two vector representations for each document by concatenating them.

2.1 Spectral Embedding

A vector space representation for documents and sentences is convenient and makes the similarity metrics such as cosine and distance readily available. However, those metrics will not work if they don't have a meaningful linguistic interpretation.

Spectral methods comprise a family of algorithms that embed terms and documents in a low-dimensional vector space. These methods use pairwise relations between the data points encoded in a similarity matrix. The main step is to find an embedding for the data that preserves the original similarities.

GLSA We use Generalized Latent Semantic Analysis (GLSA) (Matveeva et al., 2005) to compute spectral embedding for nouns. GLSA computes term vectors and since we would like to use spectral embedding for nouns, it is well-suited for our approach. GLSA extends the ideas of LSA by defining different ways to obtain the similarities matrix and has been shown to outperform LSA on a number of applications (Matveeva and Levow, 2006).

GLSA begins with a matrix of pair-wise term similarities S, computes its eigenvectors U and uses the first k of them to represent terms and documents, for details see (Matveeva et al., 2005). The justification for this approach is the theorem by Eckart and Young (Golub and Reinsch, 1971) stating that inner product similarities between the term vectors based on the eigenvectors of S represent the best element-wise approximation to the entries in S. In other words, the inner product similarity in the GLSA space preserves the semantic similarities in S.

Since our representation will try to preserve semantic similarities in S it is important to have a matrix of similarities which is linguistically motivated.

Word	Nearest Neighbors in GLSA Space					
witness	testify	prosecutor	trial	testimony	juror	eyewitness
finance	fund	bank	investment	economy	crisis	category
broadcast	television	TV	satellite	ABC	CBS	radio
hearing	hearing	judge	voice	chatter	sound	appeal
surprise	announcement	disappointment	stunning	shock	reaction	astonishment
rest	stay	remain	keep	leave	portion	economy

Table 1: Words' nearest neighbors in the GLSA semantic space.

2.2 Distributional Term Similarity

PMI Following (Turney, 2001; Matveeva et al., 2005), we use point-wise mutual information (PMI) to compute the matrix S. PMI between random variables representing the words w_i and w_j is computed as

$$PMI(w_i, w_j) = \log \frac{P(W_i = 1, W_j = 1)}{P(W_i = 1)P(W_j = 1)}. \quad (1)$$

Thus, for GLSA, $S(w_i, w_j) = PMI(w_i, w_j)$.

Co-occurrence Proximity An advantage of PMI is the notion of proximity. The co-occurrence statistics for PMI are typically computed using a sliding window. Thus, PMI will be large only for words that co-occur within a small context of fixed size.

Semantic Association vs. Synonymy Although GLSA was successfully applied to synonymy induction (Matveeva et al., 2005), we would like to point out that the GLSA discovers semantic association in a broad sense. Table 1 shows a few words from the TDT2 corpus and their nearest neighbors in the GLSA space. We can see that for "witness", "finance" and "broadcast" words are grouped into corresponding semantic classes. The nearest neighbors for "hearing" and "stay" represent their different senses. Interestingly, even for the abstract noun "surprise" the nearest neighbors are meaningful.

2.3 Document Indexing

We have two sets of the vocabulary terms: a set of nouns, N, and the other words, T. We compute *tf-idf* document vectors indexed with the words in T:

$$\vec{d_i} = (\alpha_i(w_1), \alpha_i(w_2), ..., \alpha_i(w_{|T|})), \quad (2)$$

where $\alpha_i(w_t) = \mathrm{tf}(w_t, d_i) * \mathrm{idf}(w_t)$.

We also compute a k-dimensional representation with latent concepts c_i as a weighted linear combination of GLSA term vectors $\vec{w_t}$:

$$\vec{d_i} = (c_1, ..., c_k) = \sum_{t=1:|N|} \alpha_i(w_t) * \vec{w_t}, \quad (3)$$

We concatenate these two representations to generate a hybrid indexing of documents:

$$\vec{d_i} = (\alpha_i(w_1), ..., \alpha_i(w_{|T|}), c_1, ...c_k) \quad (4)$$

In our experiments, we compute document and sentence representation using three indexing schemes: the *tf-idf* baseline, the GLSA representation and the hybrid indexing. The GLSA indexing computes term vectors for all vocabulary words; document and sentence vectors are generated as linear combinations of term vectors, as shown above.

2.4 Document similarity

One can define document similarity at different levels of semantic content. Documents can be similar because they discuss the same people or events and because they discuss related subjects and contain semantically related words. Hybrid Indexing allows us to combine both definitions of similarity. Each representation supports a different similarity measure. *tf-idf* uses term-matching, the GLSA representation uses semantic association in the latent semantic space computed for all words, and hybrid indexing uses a combination of both: term-matching for named entities and content words other than nouns combined with semantic association for nouns.

In the GLSA space, the inner product between document vectors contains all pair-wise inner product between their words, which allows one to detect semantic similarity beyond term matching:

$$\langle \vec{d_i}, \vec{d_j} \rangle = \sum_{w \in d_i} \sum_{v \in d_j} \alpha_i(w)\alpha_j(v)\langle \vec{w}, \vec{v} \rangle \quad (5)$$

If documents contain words which are different but semantically related, the inner product between the term vectors will contribute to the document similarity, as illustrated with an example in section 5.

When we compare two documents indexed with the hybrid indexing scheme, we compute a combination of similarity measures:

$$\langle \vec{d_i}, \vec{d_j} \rangle = \sum_{n_k \in d_i} \sum_{n_m \in d_j} \alpha_i(n_k)\alpha_j(n_m)\langle \vec{n_k}, \vec{n_m} \rangle + \sum_{t \in T} \alpha_i(t) * \alpha_j(t). \tag{6}$$

Document similarity contains semantic association between all pairs of nouns and uses term-matching for the rest of the vocabulary.

3 Topic Segmentation with Semantic Cohesion

Our approach to topic segmentation is based on semantic cohesion supported by the hybrid indexing. Topic segmentation approaches use either sentences (Galley et al., 2003) or blocks of words as text units (Hearst, 1994). We used both variants in our experiments. When using blocks, we computed blocks of a fixed size (typically 20 words) sliding over the documents in a fixed step size (10 or 5 words). The algorithm predicts a story boundary when the semantic cohesion between two consecutive units drops. Blocks can cross story boundaries, thus many predicted boundaries will be displaced with respect to the actual boundary.

Averaged similarity In our preliminary experiments we used the largest difference in score to predict story boundary, following the TextTiling approach (Hearst, 1994). We found, however, that in our document collection the word overlap between sentences was often not large and pair-wise similarity could drop to zero even for sentences within the same story, as will be illustrated below. We could not obtain satisfactory results with this approach.

Therefore, we used the average similarity by using a history of fixed size n. The semantic cohesion score was computed for the position between two text units, t_i and t_j as follows:

$$\text{score}(t_i, t_j) = \frac{1}{n} \sum_{k=0}^{n-1} \langle t_{i-k}, t_j \rangle \tag{7}$$

Our approach predicts story boundaries at the minima of the semantic cohesion score.

Approximating Lexical Chains One of the motivations for our cohesion score is that it approximates lexical chains, as for example in (Galley et al., 2003). Galley et al. (Galley et al., 2003) define lexical chains $R_1, .., R_N$ by considering repetitions of terms $t_1, .., t_N$ and assigning larger weights to short and compact chains. Then the lexical cohesion score between two text units t_i and t_j is based on the number of chains that overlap both of them:

$$\text{score}(t_i, t_j) = \sum_{k=1}^{N} w_k(t_i) w_k(t_j), \tag{8}$$

where $w_k(t_i) = \text{score}(R_j)$ if the chain R_j overlaps t_i and zero otherwise. Our cohesion score takes into account only the chains for words that occur in t_j and have another occurrence within n previous sentences. Due to this simplification, we compute the score based on inner products. Once we make the transition to inner products, we can use hybrid indexing and compute semantic cohesion score beyond term repetition.

4 Related Approaches

We compare our approach to the LCseg algorithm which uses lexical chains to estimate topic boundaries (Galley et al., 2003). Hybrid indexing allows us to compute semantic cohesion score rather than the lexical cohesion score based on word repetitions.

Choi at al. used LSA for segmentation (Choi et al., 2001). LSA (Deerwester et al., 1990) is a special case of spectral embedding and Choi at al. (Choi et al., 2001) used all vocabulary words to compute low-dimensional document vectors. We use GLSA (Matveeva et al., 2005) because it computes term vectors as opposed to the dual document-term representation with LSA and uses a different matrix of pair-wise similarities. Furthermore, Choi at al. (Choi et al., 2001) used clustering to predict boundaries whereas we used the average similarity scores.

s1: The **Cuban** news agency Prensa Latina called Clinton 's announcement Friday that Cubans picked up
at sea will be taken to Guantanamo Bay naval base a " new and dangerous element " in U S immigration policy.
s2: The **Cuban** government has not yet publicly reacted to Clinton 's announcement that Cuban rafters
will be turned away from the United States and taken to the U S base on the southeast tip of Cuba.
s5: The arrival of **Cuban** emigrants could be an " extraordinary aggravation " to the situation , Prensa Latina said.
s6: It noted that **Cuba** had already denounced the use of the base as a camp for Haitian refugees.
whom it had for many years encouraged to come to the United States.
s8: **Cuba** considers the land at the naval base , leased to the United States at the turn of the century,
to be illegally occupied.

s10: **General Motors Corp** said Friday it was recalling 5,600 1993-94 model Chevrolet Lumina, Pontiac
Trans Sport and Oldsmobile Silhouette minivans equipped with a power sliding door and built-in child seats.
s14: If this occurs , the shoulder belt may not properly retract , the *carmaker* said.
s15: **GM** is the only company to offer the power-sliding door.
s16: The *company* said it was not aware of any accidents or injuries related to the defect.
s17: To correct the problem , **GM** said dealers will install a modified interior trim piece that will reroute the seat belt.

Table 2: TDT. The first 17 sentences in the first file.

Existing approaches to hybrid indexing used different weights for proper nouns, nouns phrase heads and use WordNet synonyms to expand the documents, for example (Hatzivassiloglou et al., 2000; Hatzivassiloglou et al., 2001). Our approach does not require linguistic resources and learning the weights. The semantic associations between nouns are estimated using spectral embedding.

5 Experiments

5.1 Data

The first TDT collection is part of the LCseg toolkit[1] (Galley et al., 2003) and we used it to compare our approach to LCseg. We used the part of this collection with 50 files with 22 documents each.

We also used the TDT2 collection[2] of news articles from six news agencies in 1998. We used only 9,738 documents that are assigned to one topic and have length more than 50 words. We used the Lemur toolkit[3] with stemming and stop words list for the *tf-idf* indexing; we used Bikel's parser[4] to obtain the POS-tags and select nouns; we used the PLAPACK package (Bientinesi et al., 2003) to compute the eigenvalue decomposition.

Evaluation For the TDT data we use the error metric p_k (Beeferman et al., 1999) and WindowDiff (Pevzner and Hearst, 2002) which are implemented in the LCseg toolkit. We also used the TDT cost metric Cseg[5], with the default parameters P(seg)=0.3, Cmiss=1, Cfa=0.3 and distance of 50 words. All these measures look at two units (words or sentences) N units apart and evaluate how well the algorithm can predict whether there is a boundary between them or not. Lower values mean better performance for all measures.

Global vs. Local GLSA Similarity To obtain the PMI values we used the TDT2 collection, denoted as $GLSA_{local}$. Since co-occurrence statistics based on larger collections give a better approximation to linguistic similarities, we also used 700,000 documents from the English GigaWord collection, denoted as GLSA. We used a window of size 8.

5.2 Topic Segmentation

The first set of experiments was designed to evaluate the advantage of the GLSA representation over the baseline. We compare our approach to the LCseg algorithm (Galley et al., 2003) and use sentences as segmentation unit. To avoid the issue of parameters setting when the number of boundaries is not known, we provide each algorithm with the actual numbers

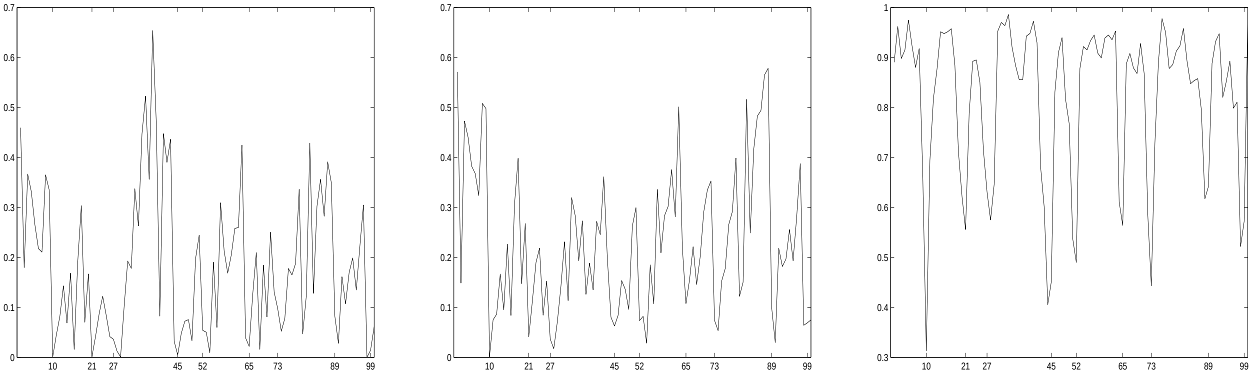

Figure 2: TDT. Pair-wise sentence similarities for *tf-idf* (left), GLSA (middle) averaged over 10 preceeding sentences; LCseg lexical cohesion scores (right). X-axis shows story boundaries.

of boundaries.

TDT We use the LCseg approach and our approach with the baseline *tf-idf* representation and the GLSA representation to segment this corpus. Table 2 shows a few sentences. Many content words are repeated, so the lexical chains is definitely a sound approach. As shown in Table 2, in the first story the word “Cuba” or “Cuban” is repeated in every sentence thus generating a lexical chain. On the topic boundary, the word overlap between sentences is very small. At the same time, the repetition of words may also be interrupted within a story: sentence 5, 6 and sentences 14, 15, 16 have little word overlap. LCseg deals with this by defining several parameters to control chain length and gaps. This simple example illustrates the potential benefit of semantic cohesion. Table 2 shows that “General Motors” or “GM” are not repeated in every sentence of the second story. However, “GM”, “carmaker” and “company” are semantically related. Making this information available to the segmentation algorithm allows it to establish a connection between each sentence of the second story.

We computed pair-wise sentence similarities between pairs of consecutive sentences in the *tf-idf* and GLSA representations. Figure 1 shows the similarity values plotted for each sentence break. The pairwise similarities based on term-matching are very spiky and there are many zeros within the story. The GLSA-based similarity makes the dips in the similarities at the boundaries more prominent. The last plot gives the details for the sentences in table 2. In the *tf-idf* representation sentences without word overlap receive zero similarity but the GLSA representation is able to use the semantic association between between “emigrants” and “refugees” for sentences 5 and 6, and also the semantic association between “carmaker” and “company” for sentences 14

Measure	*tf-idf*	GLSA	LCseg
Pmiss	0.29	0.19	N/A
Pfa	0.14	0.09	N/A
Cseg	0.18	0.08	N/A
p$_k$	0.24	0.17	0.07
wd	0.27	0.21	0.10

Table 3: TDT segmentation results.

and 15.

This effect increases as we use the semantic cohesion score as in equation 7. Figure 2 shows the similarity values for *tf-idf* and GLSA and also the lexical cohesion scores computed by LCseg. The GLSA-based similarities are not quite as smooth as the LCseg scores, but they correctly discover the boundaries. LCseg parameters are fine-tuned for this document collection. We used a general TDT2 GLSA representation for this collection, and the only segmentation parameter we used is to avoid placing next boundary within n=3 sentences of the previous one. For this reason the predicted boundary may be one sentence off the actual boundary. These results are summarized in Table 3. The GLSA representation performs significantly better than the *tf-idf* baseline. Its p_k and WindowDiff scores with default parameters for LCseg are worse than for LCseg. We attribute it to the fact that we did not fine-tuned our method to this collection and that boundaries are often placed one position off the actual boundary.

TDT2 For this collection we used three different indexing schemes: the *tf-idf* baseline, the GLSA representation and the hybrid indexing. Each representation supports a different similarity measure. Our TDT experiments showed that the semantic cohesion score based on the GLSA representation improves the segmentation results. The variant of the TDT corpus we used is rather small and well-balanced, see (Galley et al., 2003) for details. In the second phase of experiments we evaluate our approach on the larger TDT2 corpus. The experiments were designed to address the following issues:

- performance comparison between GLSA and Hybrid indexing representations. As mentioned before, GLSA embeds all words in a low-dimensional space. Whereas semantic classes for nouns have theoretical linguistic justification, it is harder to motivate a latent space representation for example for proper nouns. Therefore, we want to evaluate the advantage of using spectral embedding only for nouns.

- collection dependence of similarities. The similarity matrix S is computed using the TDT2 corpus ($GLSA_{local}$) and using the larger GigaWord corpus. The larger corpus provides more reliable co-occurrence statistics. On the other hand, word distribution is different from that in the TDT2 corpus. We wanted to evaluate whether semantic similarities are collection independent.

#b known			
Method	Pmiss	Pfa	Cseg
tf-idf	0.52	0.14	0.19
GLSA	0.4	0.1	0.14
GLSA_$local$	0.44	0.12	0.16
Hybrid	0.34	0.10	0.12
Hybrid_$local$	0.38	0.09	0.13
LCseg	0.80	0.19	0.28
#b unknown			
Method	Pmiss	Pfa	Cseg
tf-idf	0.42	0.2	0.17
GLSA	0.37	0.13	0.14
GLSA_$local$	0.35	0.19	0.14
Hybrid	0.26	0.16	0.11
Hybrid_$local$	0.27	0.18	0.12

Table 4: TDT2 segmentation results. Sliding blocks with size 20 and stepsize 10; similarity averaged over 10 preceeding blocks.

Table 4 shows the performance evaluation. We show the results computed using blocks containing 20 words (after preprocessing) with step size 10. We tried other parameter values but did not achieve better performance, which is consistent with other research (Hearst, 1994; Galley et al., 2003). We show the results for two settings: predict a known number of boundaries, and predict boundaries using a threshold. In our experiments we used the average of the smallest N scores as threshold, $N = 4000$ showing best results.

The spectral embedding based representations (GLSA, Hybrid) significantly outperform the baseline. This confirms the advantage of the semantic cohesion score vs. term-matching. Hybrid indexing outperforms the GLSA representation supporting our intuition that semantic association is best defined for nouns.

We used the GigaWord corpus to obtain the pair-wise word associations for the GLSA and Hybrid representations. We also computed GLSA$_{local}$ and Hybrid$_{local}$ using the TDT2 corpus to obtain the pair-wise word associations. The co-occurrence statistics based on the GigaWord corpus provide more reliable estimations of semantic association despite the difference in term distribution. The difference is larger for the GLSA case when we compute the embedding for all words, GLSA performs better than GLSA$_{local}$. Hybrid$_{local}$ performs only slightly worse than Hybrid. This seems to support the claim that semantic associations between nouns are largely collection independent. On the other hand, semantic associations for proper names are collection dependent at least because the collections are static but the semantic relations of proper names may change over time. The semantic space for a name of a president, for example, is different for the period of time of his presidency and for the time before and after that.

Disappointingly, we could not achieve good results with LCseg. It tends to split stories into short paragraphs. Hybrid indexing could achieve results comparable to state-of-the art approaches, see (Fiscus et al., 1998) for an overview.

6 Conclusion and Future Work

We presented a topic segmentation approach based on semantic cohesion scores. Our approach is domain independent, does not require training or use of lexical resources. The scores are computed based on the hybrid document indexing which uses spectral embedding in the space of latent concepts for nouns and keeps proper nouns and other specifics of the documents collections unchanged. We approximate the lexical chains approach by simplifying the definition of a chain which allows us to use inner products as basis for the similarity score. The similarity score takes into account semantic relations between nouns beyond term matching. This semantic cohesion approach showed good results on the topic segmentation task.

We intend to extend the hybrid indexing approach by considering more vocabulary subsets. Syntactic similarity is more appropriate for verbs, for example, than co-occurrence. As a next step, we intend to embed verbs using syntactic similarity. It would also be interesting to use lexical chains for proper names and learn the weights for different similarity scores.

Abstract

We present a method for improving word alignment for statistical syntax-based machine translation that employs a syntactically informed alignment model closer to the translation model than commonly-used word alignment models. This leads to extraction of more useful linguistic patterns and improved BLEU scores on translation experiments in Chinese and Arabic.

1 Methods of statistical MT

Roughly speaking, there are two paths commonly taken in statistical machine translation (Figure 1). The idealistic path uses an unsupervised learning algorithm such as EM (Demptser et al., 1977) to learn parameters for some proposed translation model from a bitext training corpus, and then directly translates using the weighted model. Some examples of the idealistic approach are the direct IBM word model (Berger et al., 1994; Germann et al., 2001), the phrase-based approach of Marcu and Wong (2002), and the syntax approaches of Wu (1996) and Yamada and Knight (2001). Idealistic approaches are conceptually simple and thus easy to relate to observed phenomena. However, as more parameters are added to the model the idealistic approach has not scaled well, for it is increasingly difficult to incorporate large amounts of training data efficiently over an increasingly large search space. Additionally, the EM procedure has a tendency to overfit its training data when the input units have varying explanatory powers, such as variable-size phrases or variable-height trees.

The realistic path also learns a model of translation, but uses that model only to obtain Viterbi word-for-word alignments for the training corpus. The bitext and corresponding alignments are then used as input to a pattern extraction algorithm, which yields a set of patterns or rules for a second translation model (which often has a wider parameter space than that used to obtain the word-for-word alignments). Weights for the second model are then set, typically by counting and smoothing, and this weighted model is used for translation. Realistic approaches scale to large data sets and have yielded better BLEU performance than their idealistic counterparts, but there is a disconnect between the first model (hereafter, the *alignment model*) and the second (the *translation model*). Examples of realistic systems are the phrase-based ATS system of Och and Ney (2004), the phrasal-syntax hybrid system Hiero (Chiang, 2005), and the GHKM syntax system (Galley et al., 2004; Galley et al., 2006). For an alignment model, most of these use the Aachen HMM approach (Vogel et al., 1996), the implementation of IBM Model 4 in GIZA++ (Och and Ney, 2000) or, more recently, the semi-supervised EMD algorithm (Fraser and Marcu, 2006).

The two-model approach of the realistic path has undeniable empirical advantages and scales to large data sets, but new research tends to focus on development of higher order translation models that are informed only by low-order alignments. We would like to add the analytic power gained from modern translation models to the underlying alignment model without sacrificing the efficiency and empirical gains of the two-model approach. By adding the

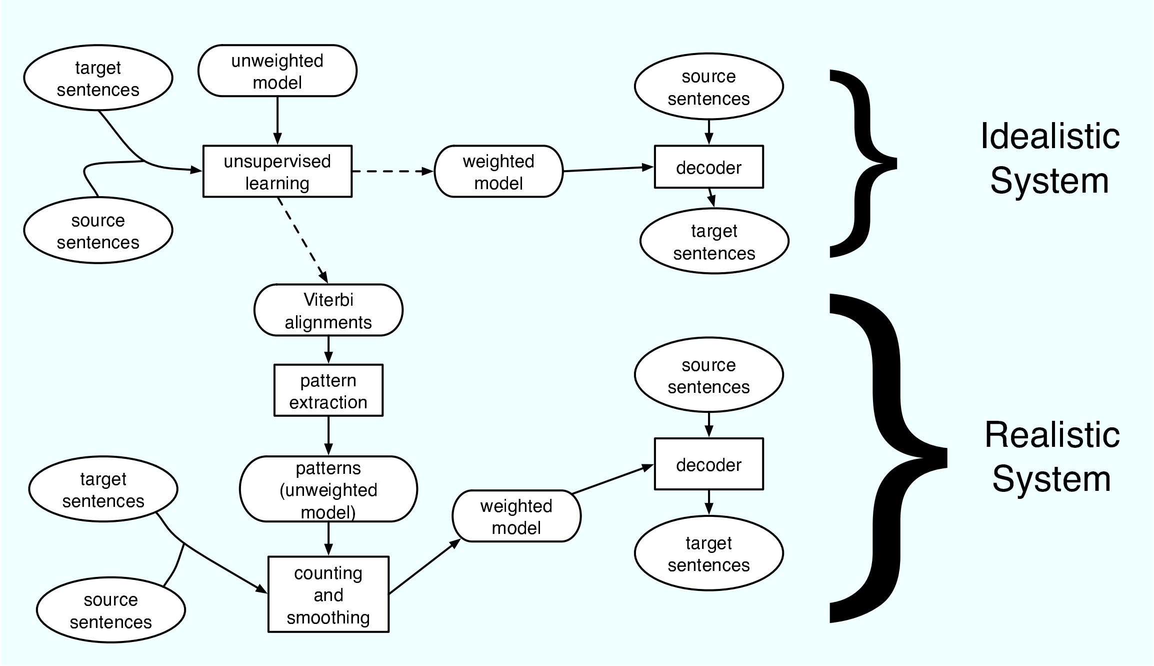

Figure 1: General approach to idealistic and realistic statistical MT systems

syntactic information used in the translation model to our alignment model we may improve alignment quality such that rule quality and, in turn, system quality are improved. In the remainder of this work we show how a touch of idealism can improve an existing realistic syntax-based translation system.

2 Multi-level syntactic rules for syntax MT

Galley et al. (2004) and Galley et al. (2006) describe a syntactic translation model that relates English trees to foreign strings. The model describes joint production of a (tree, string) pair via a non-deterministic selection of weighted rules. Each rule has an English tree fragment with variables and a corresponding foreign string fragment with the same variables. A series of rules forms an explanation (or *derivation*) of the complete pair.

As an example, consider the parsed English and corresponding Chinese at the top of Figure 2. The three columns underneath the example are different rule sequences that can explain this pair; there are many other possibilities. Note how rules specify rotation (e.g. R10, R5), direct translation (R12, R8), insertion and deletion (R11, R1), and tree traversal (R7, R15). Note too that the rules explain variable-size fragments (e.g. R6 vs. R14) and thus the possible *derivation trees* of rules that explain a sentence pair have varying sizes. The smallest such derivation tree has a single large rule (which does not appear in Figure 2; we leave the description of such a rule as an exercise for the reader). A string-to-tree decoder constructs a *derivation forest* of derivation trees where the right sides of the rules in a tree, taken together, explain a candidate source sentence. It then outputs the English tree corresponding to the highest-scoring derivation in the forest.

3 Introducing syntax into the alignment model

We now lay the ground for a syntactically motivated alignment model. We begin by reviewing an alignment model commonly seen in realistic MT systems and compare it to a syntactically-aware alignment model.

3.1 The traditional IBM alignment model

IBM Model 4 (Brown et al., 1993) learns a set of 4 probability tables to compute $p(f|e)$ given a foreign sentence f and its target translation e via the following (greatly simplified) generative story:

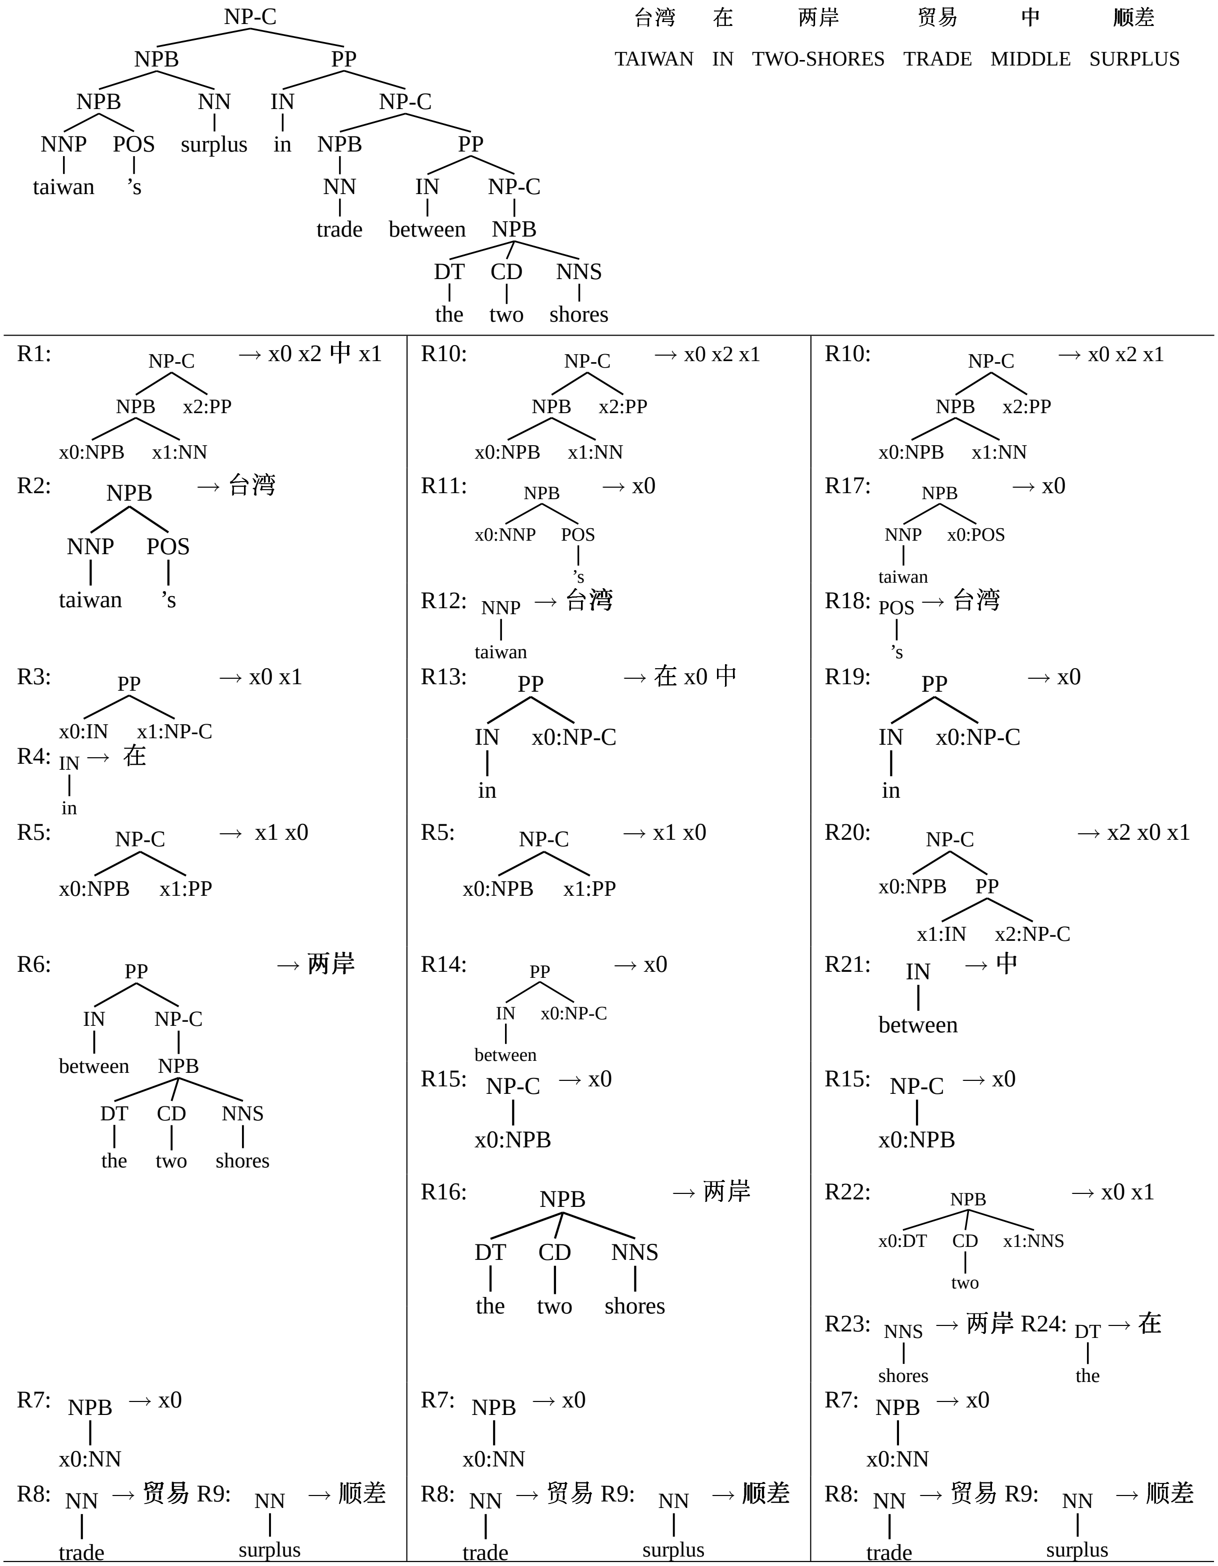

Figure 2: A (English tree, Chinese string) pair and three different sets of multilevel tree-to-string rules that can explain it; the first set is obtained from bootstrap alignments, the second from this paper’s re-alignment procedure, and the third is a viable, if poor quality, alternative that is not learned.

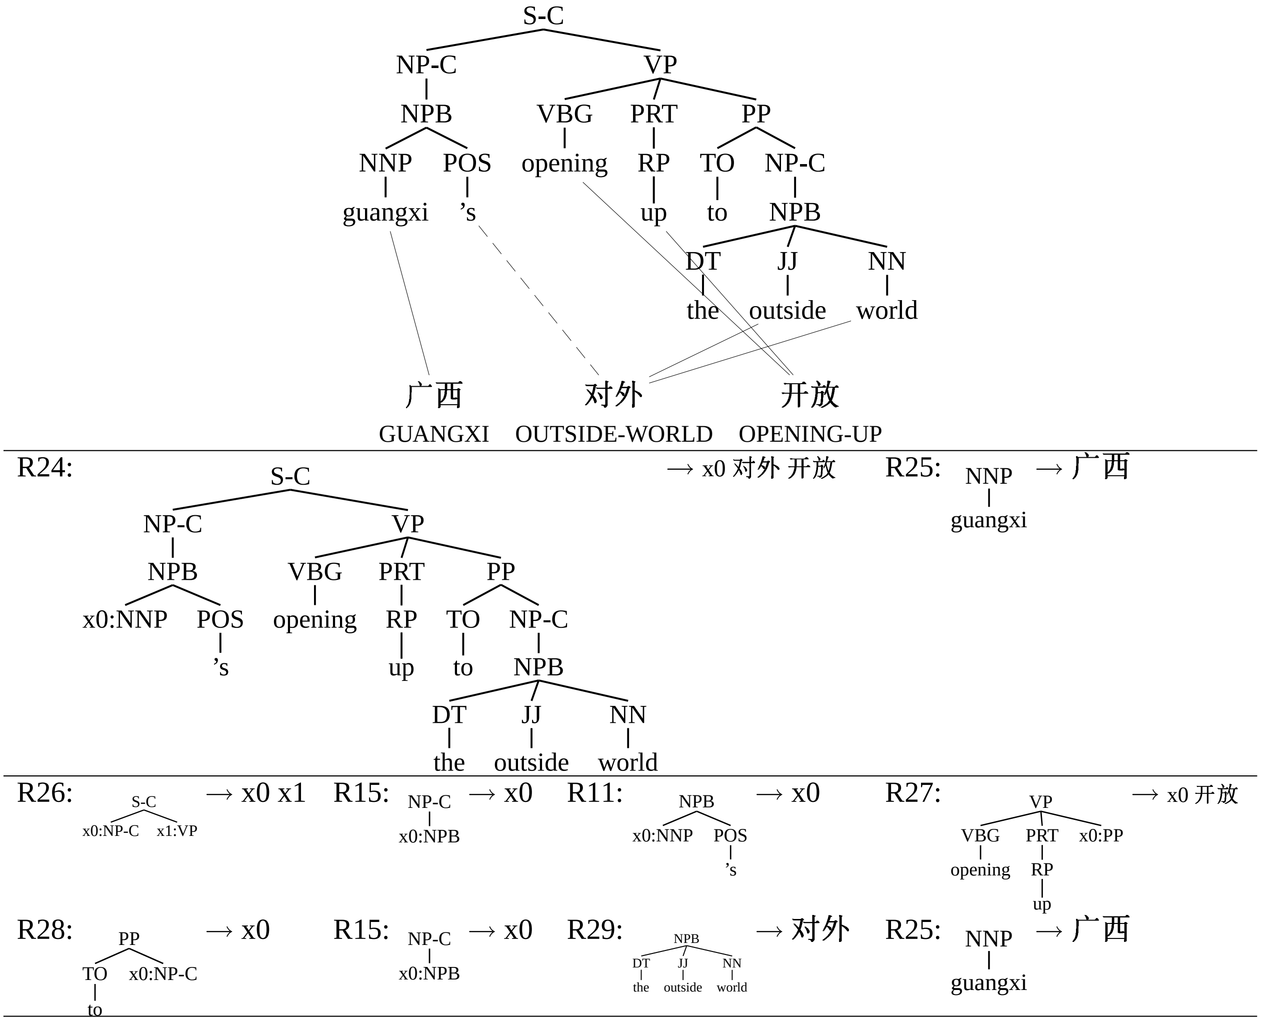

Figure 3: The impact of a bad alignment on rule extraction. Including the alignment link indicated by the dotted line in the example leads to the rule set in the second row. The re-alignment procedure described in Section 3.2 learns to prefer the rule set at bottom, which omits the bad link.

1. A fertility y for each word e_i in e is chosen with probability $p_{fert}(y|e_i)$.
2. A null word is inserted next to each fertility-expanded word with probability p_{null}.
3. Each token e_i in the fertility-expanded word and null string is translated into some foreign word f_i in f with probability $p_{trans}(f_i|e_i)$.
4. The position of each foreign word f_i that was translated from e_i is changed by Δ (which may be positive, negative, or zero) with probability $p_{distortion}(\Delta|\mathcal{A}(e_i), \mathcal{B}(f_i))$, where $\mathcal{A}$ and $\mathcal{B}$ are functions over the source and target vocabularies, respectively.

Brown et al. (1993) describes an EM algorithm for estimating values for the four tables in the generative story. However, searching the space of all possible alignments is intractable for EM, so in practice the procedure is bootstrapped by models with narrower search space such as IBM Model 1 (Brown et al., 1993) or Aachen HMM (Vogel et al., 1996).

3.2 A syntax re-alignment model

Now let us contrast this commonly used model for obtaining alignments with a syntactically motivated alternative. We recall the rules described in Section 2. Our model learns a single probability table to compute $p(etree, f)$ given a foreign sentence f and a parsed target translation $etree$. In the following generative story we assume a starting variable with syntactic type v.

1. Choose a rule r to replace v, with probability $p_{rule}(r|v)$.
2. For each variable with syntactic type v_i in the partially completed (tree, string) pair, continue to choose rules r_i with probability $p_{rule}(r_i|v_i)$ to replace these variables until there are no variables remaining.

In Section 5.1 we discuss an EM learning procedure for estimating these rule probabilities.

As in the IBM approach, we must mitigate intractability by limiting the parameter space searched, which is potentially much wider than in the word-to-word case. We would like to supply to EM all possible rules that explain the training data, but this implies a rule relating each possible tree fragment to each possible string fragment, which is infeasible. We follow the approach of bootstrapping from a model with a narrower parameter space as is done in, e.g. Och and Ney (2000) and Fraser and Marcu (2006).

To reduce the model space we employ the rule acquisition technique of Galley et al. (2004), which obtains rules given a (tree, string) pair as well as an initial alignment between them. We are agnostic about the source of this bootstrap alignment and in Section 5 present results based on several different bootstrap alignment qualities. We require an initial set of alignments, which we obtain from a word-for-word alignment procedure such as GIZA++ or EMD. Thus, we are not aligning input data, but rather *re-aligning* it with a syntax model.

4 The appeal of a syntax alignment model

Consider the example of Figure 2 again. The leftmost derivation is obtained from the bootstrap alignment set. This derivation is reasonable but there are some poorly motivated rules, from a linguistic standpoint. The Chinese word 两岸 roughly means "the two shores" in this context, but the rule R6 learned from the alignment incorrectly includes "between". However, other sentences in the training corpus have the correct alignment, which yields rule R16. Meanwhile, rules R13 and R14, learned from yet other sentences in the training corpus, handle the 在 ... 中 structure (which roughly translates to "in between"), thus allowing the middle derivation.

		SENTENCE PAIRS	
	DESCRIPTION	CHINESE	ARABIC
TUNE	NIST 2002 short	925	696
TEST	NIST 2003	919	663

Table 1: Tuning and testing data sets for the MT system described in Section 5.2.

EM distributes rule probabilities in such a way as to maximize the probability of the training corpus. It thus prefers to use one rule many times instead of several different rules for the same situation over several sentences, if possible. R6 is a possible rule in 46 of the 329,031 sentence pairs in the training corpus, while R16 is a possible rule in 100 sentence pairs. Well-formed rules are more usable than ill-formed rules and the partial alignments behind these rules, generally also well-formed, become favored as well. The top row of Figure 3 contains an example of an alignment learned by the bootstrap alignment model that includes an incorrect link. Rule R24, which is extracted from this alignment, is a poor rule. A set of commonly seen rules learned from other training sentences provide a more likely explanation of the data, and the consequent alignment omits the spurious link.

5 Experiments

In this section, we describe the implementation of our semi-idealistic model and our means of evaluating the resulting re-alignments in an MT task.

5.1 The re-alignment setup

We begin with a training corpus of Chinese-English and Arabic-English bitexts, the English side parsed by a reimplementation of the standard Collins model (Bikel, 2004). In order to acquire a syntactic rule set, we also need a bootstrap alignment of each training sentence. We use an implementation of the GHKM

BOOTSTRAP GIZA CORPUS		RE-ALIGNMENT EXPERIMENT

algorithm (Galley et al., 2004) to obtain a rule set for each bootstrap alignment.

Now we need an EM algorithm for learning the parameters of the rule set that maximize $\prod_{corpus} p(tree, string)$. Such an algorithm is presented by Graehl and Knight (2004). The algorithm consists of two components: DERIV, which is a procedure for constructing a packed forest of derivation trees of rules that explain a (tree, string) bitext corpus given that corpus and a rule set, and TRAIN, which is an iterative parameter-setting procedure.

We initially attempted to use the top-down DERIV algorithm of Graehl and Knight (2004), but as the constraints of the derivation forests are largely lexical, too much time was spent on exploring dead-ends. Instead we build derivation forests using the following sequence of operations:

1. Binarize rules using the synchronous binarization algorithm for tree-to-string transducers described in Zhang et al. (2006).
2. Construct a parse chart with a CKY parser simultaneously constrained on the foreign string and English tree, similar to the bilingual parsing of Wu (1997) [1].
3. Recover all reachable edges by traversing the chart, starting from the topmost entry.

Since the chart is constructed bottom-up, leaf lexical constraints are encountered immediately, resulting in a narrower search space and faster running time than the top-down DERIV algorithm for this application. Derivation forest construction takes around 400 hours of cumulative machine time (4-processor machines) for Chinese. The actual running of EM iterations (which directly implements the TRAIN algorithm of Graehl and Knight (2004)) takes about 10 minutes, after which the Viterbi derivation trees are directly recoverable. The Viterbi derivation tree tells us which English words produce which Chinese words, so we can extract a word-to-word alignment from it. We summarize the approach described in this paper as:

1. Obtain bootstrap alignments for a training corpus using GIZA++.
2. Extract rules from the corpus and alignments using GHKM, noting the partial alignment that is used to extract each rule.
3. Construct derivation forests for each (tree, string) pair, ignoring the alignments, and run EM to obtain Viterbi derivation trees, then use the annotated partial alignments to obtain Viterbi alignments.
4. Use the new alignments as input to the MT system described below.

5.2 The MT system setup

A truly idealistic MT system would directly apply the rule weight parameters learned via EM to a machine translation task. As mentioned in Section 1, we maintain the two-model, or realistic approach. Below we briefly describe the translation model, focusing on comparison with the previously described alignment model. Galley et al. (2006) provides a more complete description of the translation model and DeNeefe et al. (2007) provides a more complete description of the end-to-end translation pipeline.

Although in principle the re-alignment model and translation model learn parameter weights over the same rule space, in practice we limit the rules used for re-alignment to the set of smallest rules that explain the training corpus and are consistent with the bootstrap alignments. This is a compromise made to reduce the search space for EM. The translation model learns multiple derivations of rules consistent with the re-alignments for each sentence, and learns

[1] In the cases where a rule is not synchronous-binarizable standard left-right binarization is performed and proper permutation of the disjoint English tree spans must be verified when building the part of the chart that uses this rule.

weights for these by counting and smoothing. A dozen other features are also added to the rules. We obtain weights for the combinations of the features by performing minimum error rate training (Och, 2003) on held-out data. We then use a CKY decoder to translate unseen test data using the rules and tuned weights. Table 1 summarizes the data used in tuning and testing.

5.3 Initial results

An initial re-alignment experiment shows a reasonable rise in BLEU scores from the baseline (Table 2), but closer inspection of the rules favored by EM implies we can do even better. EM has a tendency to favor few large rules over many small rules, even when the small rules are more useful. Referring to the rules in Figure 2, note that possible derivations for (taiwan 's, 台湾)[2] are R2, R11-R12, and R17-R18. Clearly the third derivation is not desirable, and we do not discuss it further. Between the first two derivations, R11-R12 is preferred over R2, as the conditioning for possessive insertion is not related to the specific Chinese word being inserted. Of the 1,902 sentences in the training corpus where this pair is seen, the bootstrap alignments yield the R2 derivation 1,649 times and the R11-R12 derivation 0 times. Re-alignment does not change the result much; the new alignments yield the R2 derivation 1,613 times and again never choose R11-R12. The rules in the second derivation themselves are not rarely seen – R11 is in 13,311 forests *other* than those where R2 is seen, and R12 is in 2,500 additional forests. EM gives R11 a probability of $e^{-7.72}$ – better than 98.7% of rules, and R12 a probability of $e^{-2.96}$. But R2 receives a probability of $e^{-6.32}$ and is preferred over the R11-R12 derivation, which has a combined probability of $e^{-10.68}$.

5.4 Making EM fair

The preference for shorter derivations containing large rules over longer derivations containing small rules is due to a general tendency for EM to prefer derivations with few atoms. Marcu and Wong (2002) note this preference but consider the phenomenon a feature, rather than a bug. Zollmann and Sima'an (2005) combat the overfitting aspect for parsing by using a held-out corpus and a straight maximum likelihood estimate, rather than EM. We take a modeling approach to the phenomenon.

As the probability of a derivation is determined by the product of its atom probabilities, longer derivations with more probabilities to multiply have an inherent disadvantage against shorter derivations, all else being equal. EM is an iterative procedure and thus such a bias can lead the procedure to converge with artificially raised probabilities for short derivations and the large rules that comprise them. The relatively rare applicability of large rules (and thus lower observed partial counts) does not overcome the inherent advantage of large coverage. To combat this, we introduce size terms into our generative story, ensuring that all competing derivations for the

[2] The Chinese gloss is simply "taiwan".

LANGUAGE PAIR	TYPE	RULES	TUNE	TEST

Table 4: Re-alignment performance with semi-supervised EMD bootstrap alignments

same sentence contain the same number of atoms:

1. Choose a rule size s with cost $c_{size}(s)^{s-1}$.
2. Choose a rule r (of size s) to replace the start symbol with probability $p_{rule}(r|s, v)$.
3. For each variable in the partially completed (tree, string) pair, continue to choose sizes followed by rules, recursively to replace these variables until there are no variables remaining.

This generative story changes the derivation comparison from R2 vs R11-R12 to S2-R2 vs R11-R12, where S2 is the atom that represents the choice of size 2 (the size of a rule in this context is the number of non-leaf and non-root nodes in its tree fragment). Note that the variable number of inclusions implied by the exponent in the generative story above ensures that all derivations have the same size. For example, a derivation with one size-3 rule, a derivation with one size-2 and one size-1 rule, and a derivation with three size-1 rules would each have three atoms. With this revised model that allows for fair comparison of derivations, the R11-R12 derivation is chosen 1636 times, and S2-R2 is not chosen. R2 does, however, appear in the translation model, as the expanded rule extraction described in Section 5.2 creates R2 by joining R11 and R12.

The probability of size atoms, like that of rule atoms, is decided by EM. The revised generative story tends to encourage smaller sizes by virtue of the exponent. This does not, however, simply ensure the largest number of rules per derivation is used in all cases. Ill-fitting and poorly-motivated rules such as R22, R23, and R24 in Figure 2 are not preferred over R16, even though they are smaller. However, R14 and R16 are preferred over R6, as the former are useful rules. Although the modified model does not sum to 1, it leads to an improvement in BLEU score, as can be seen in the last row of Table 2.

5.5 Results

We performed primary experiments on two different bootstrap setups in two languages: the initial experiment uses the same data set for the GIZA++ initial alignment as is used in the re-alignment, while an experiment on better quality bootstrap alignments uses a much larger data set. For each bootstrapping in each language we compared the baseline of using these alignments directly in an MT system with the experiment of using the alignments obtained from the re-alignment procedure described in Section 5.4. For each experiment we report: the number of rules extracted by the expanded GHKM algorithm of Galley et al. (2006) for the translation model, converged BLEU scores on the tuning set, and finally BLEU performance on the held-out test set. Data set specifics for the GIZA++ bootstrapping and BLEU results are summarized in Table 3.

5.6 Discussion

The results presented demonstrate we are able to improve on unsupervised GIZA++ alignments by about 1 BLEU point for Chinese and around 0.4 BLEU point for Arabic using an additional unsupervised algorithm that requires no human aligned data. If human-aligned data is available, the EMD algorithm provides higher baseline alignments than GIZA++ that have led to better MT performance (Fraser and Marcu, 2006). As a further experiment we repeated the experimental conditions from Table 3, this time bootstrapped with the semi-supervised EMD method, which uses the larger bootstrap GIZA corpora described in Table 3 and an additional 64,469/48,650 words of hand-aligned English-Chinese and 43,782/31,457 words of hand-aligned English-Arabic. The results of this advanced experiment are in Table 4. We show a 0.42 gain in BLEU for Arabic, but no movement for Chinese. We believe increasing the size of the re-alignment corpora will increase BLEU gains in this experimental condition, but leave those results for future work.

We can see from the results presented that the impact of the syntax-aware re-alignment procedure of Section 3.2, coupled with the addition of size parameters to the generative story from Section 5.4 serves to remove links from the bootstrap alignments that cause less useful rules to be extracted, and thus increase the overall quality of the rules, and hence the system performance. We thus see the benefit to including syntax in an alignment model, bringing the two models of the realistic machine translation path somewhat closer together.

Abstract

In this paper we explore the use of selectional preferences for detecting non-compositional verb-object combinations. To characterise the arguments in a given grammatical relationship we experiment with three models of selectional preference. Two use WordNet and one uses the entries from a distributional thesaurus as classes for representation. In previous work on selectional preference acquisition, the classes used for representation are selected according to the coverage of argument tokens rather than being selected according to the coverage of argument types. In our distributional thesaurus models and one of the methods using WordNet we select classes for representing the preferences by virtue of the number of argument types that they cover, and then only tokens under these classes which are representative of the argument head data are used to estimate the probability distribution for the selectional preference model. We demonstrate a highly significant correlation between measures which use these 'type-based' selectional preferences and compositionality judgements from a data set used in previous research. The type-based models perform better than the models which use tokens for selecting the classes. Furthermore, the models which use the automatically acquired thesaurus entries produced the best results. The correlation for the thesaurus models is stronger than any of the individual features used in previous research on the same dataset.

1 Introduction

Characterising the semantic behaviour of phrases in terms of compositionality has particularly attracted attention in recent years (Lin, 1999; Schone and Jurafsky, 2001; Bannard, 2002; Bannard et al., 2003; Baldwin et al., 2003; McCarthy et al., 2003; Bannard, 2005; Venkatapathy and Joshi, 2005). Typically the phrases are putative multiwords and non-compositionality is viewed as an important feature of many such "words with spaces" (Sag et al., 2002). For applications such as paraphrasing, information extraction and translation, it is essential to take the words of non-compositional phrases together as a unit because the meaning of a phrase cannot be obtained straightforwardly from the constituent words. In this work we are investigate methods of determining semantic compositionality of verb-object [1] combinations on a continuum following previous research in this direction (McCarthy et al., 2003; Venkatapathy and Joshi, 2005).

Much previous research has used a combination of statistics and distributional approaches whereby distributional similarity is used to compare the constituents of the multiword with the multiword itself. In this paper, we will investigate the use of selectional preferences of verbs. We will use the preferences to find atypical verb-object combinations as we anticipate that such combinations are more likely to be non-compositional.

[1] We use object to refer to direct objects.

Proceedings of the 2007 Joint Conference on Empirical Methods in Natural Language Processing and Computational Natural Language Learning, pp. 369–379, Prague, June 2007. ©2007 Association for Computational Linguistics

Selectional preferences of predicates have been modelled using the man-made thesaurus WordNet (Fellbaum, 1998), see for example (Resnik, 1993; Li and Abe, 1998; Abney and Light, 1999; Clark and Weir, 2002). There are also distributional approaches which use co-occurrence data to cluster distributionally similar words together. The cluster output can then be used as classes for selectional preferences (Pereira et al., 1993), or one can directly use frequency information from distributionally similar words for smoothing (Grishman and Sterling, 1994).

We used three different types of probabilistic models, which vary in the classes selected for representation over which the probability distribution of the argument heads [2] is estimated. Two use WordNet and the other uses the entries in a thesaurus of distributionally similar words acquired automatically following (Lin, 1998). The first method is due to Li and Abe (1998). The classes over which the probability distribution is calculated are selected according to the minimum description length principle (MDL) which uses the argument head tokens for finding the best classes for representation. This method has previously been tried for modelling compositionality of verb-particle constructions (Bannard, 2002).

The other two methods (we refer to them as 'type-based') also calculate a probability distribution using argument head tokens but they select the classes over which the distribution is calculated using the number of argument head types (of a verb in a corpus) in a given class, rather than the number of argument head tokens in contrast to previous WordNet models (Resnik, 1993; Li and Abe, 1998; Clark and Weir, 2002). For example, if the object slot of the verb *park* contains the argument heads { *car, car, car, car, van, jeep* } then the type-based models use the word type "*car*" only once when determining the classes over which the probability distribution is to be estimated. Classes are selected which maximise the number of types that they cover, rather than the number of tokens. This is done to avoid the selectional preferences being heavily influenced by noise from highly frequent arguments which may be polysemous and some or all of their meanings may not be semantically related to the 'prototypical' arguments of the verb. For example *car* has a **gondola** sense in WordNet.

The third method uses entries in a distributional thesaurus rather than classes from WordNet. The entries used as classes for representation are selected by virtue of the number of argument types they encompass. As with the WordNet models, the tokens are used to estimate a probability distribution over these entries.

In the next section, we discuss related work on identifying compositionality. In section 3, we describe the methods we are using for acquiring our models of selectional preference. In section 4, we test our models on a dataset used in previous research. We compare the three types of models individually and also investigate the best performing model when used in combination with other features used in previous research. We conclude in section 5.

2 Related Work

Most previous work using distributional approaches to compositionality either contrasts distributional information of candidate phrases with constituent words (Schone and Jurafsky, 2001; Bannard et al., 2003; Baldwin et al., 2003; McCarthy et al., 2003) or uses distributionally similar words to detect non-productive phrases (Lin, 1999).

Lin (1999) used his method (Lin, 1998) for automatic thesaurus construction. He identified candidate phrases involving several open-class words output from his parser and filtered these by the log-likelihood statistic. Lin proposed that if there is a phrase obtained by substitution of either the head or modifier in the phrase with a 'nearest neighbour' from the thesaurus then the mutual information of this and the original phrase must be significantly different for the original phrase to be considered non-compositional. He evaluated the output manually.

As well as distributional similarity, researchers have used a variety of statistics as indicators of non-compositionality (Blaheta and Johnson, 2001; Krenn and Evert, 2001). Fazly and Stevenson (2006) use statistical measures of syntactic behaviour to gauge whether a verb and noun combination is likely to be a idiom. Although they are not specifically detecting compositionality, there is a strong corre-

[2] Argument heads are the nouns occurring in the object slot of the target verb.

lation between syntactic rigidity and semantic idiosyncrasy.

Venkatapathy and Joshi (2005) combine different statistical and distributional methods using support vector machines (SVMs) for identifying non-compositional verb-object combinations. They explored seven features as measures of compositionality:

1. frequency
2. pointwise mutual information (Church and Hanks, 1990),
3. least mutual information difference with similar collocations, based on (Lin, 1999) and using Lin's thesaurus (Lin, 1998) for obtaining the similar collocations.
4. The distributed frequency of an object, which takes an average of the frequency of occurrence with an object over all verbs occurring with the object above a threshold.
5. distributed frequency of an object, using the verb, which considers the similarity between the target verb and the verbs occurring with the target object above the specified threshold.
6. a latent semantic approach (LSA) based on (Schütze, 1998; Baldwin et al., 2003) and considering the dissimilarity of the verb-object pair with its constituent verb
7. the same LSA approach, but considering the similarity of the verb-object pair with the verbal form of the object (to capture support verb constructions e.g. *give a smile*

Venkatapathy and Joshi (2005) produced a dataset of verb-object pairs with human judgements of compositionality. We say more about this dataset and Venkatapathy and Joshi's results in section 4 since we use the dataset for our experiments.

In this paper, we investigate the use of selectional preferences to detect compositionality. Bannard (2002) did some pioneering work to try and establish a link between the compositionality of verb particle constructions and the selectional preferences of the multiword and its constituent verb. His results were hampered by models based on (Li and Abe, 1998) which involved rather uninformative models at the roots of WordNet. There are several reasons for this. The classes for the model are selected using MDL by compromising between a simple model with few classes and one which explains the data well. The models are particularly affected by the quantity of data available (Wagner, 2002). Also noise from frequent but idiosyncratic or polysemous arguments weakens the signal. There is scope for experimenting with other approaches such as (Clark and Weir, 2002), however, we feel a type-based approach is worthwhile to avoid the noise introduced from frequent but polysemous arguments and bias from highly frequent arguments which might be part of a multiword rather than a prototypical argument of the predicate in question, for example *eat hat*. In contrast to Bannard, our experiments are with verb-object combinations rather than verb particle constructions. We compare Li and Abe models with WordNet models which use the number of argument types to obtain the classes for representation of the selectional preferences. In addition to experiments with these WordNet models, we propose models using entries in distributional thesauruses for representing preferences.

3 Three Methods for Acquiring Selectional Preferences

All models were acquired from verb-object data extracted using the RASP parser (Briscoe and Carroll, 2002) from the 90 million words of written English from the BNC (Leech, 1992). We extracted verb and common noun tuples where the noun is the argument head of the object relation. The parser was also used to extract the grammatical relation data used for acquisition of the thesaurus described below in section 3.3.

3.1 TCMS

This approach is a reimplementation of Li and Abe (1998). Each selectional preference model (referred to as a tree cut model, or TCM) comprises a set of disjunctive noun classes selected from all the possibilities in the WordNet hyponym hierarchy [3] using MDL (Rissanen, 1978). The TCM covers all the

[3] We use WordNet version 2.1 for the work in this paper.

noun senses in the WordNet hierarchy and is associated with a probability distribution over these noun senses in the hierarchy reflecting the argument head data occurring in the given grammatical relationship with the specified verb. MDL finds the classes in the TCM by considering the cost measured in bits of describing both the model and the argument head data encoded in the model. A compromise is made by having as simple a model as possible using classes further up the hierarchy whilst also providing a good model for the set of argument head tokens (TK).

The classes are selected by recursing from the top of the WordNet hierarchy comparing the cost (or description length) of using the mother class to the cost of using the hyponym daughter classes. In any path, the mother is preferred unless using the daughters would reduce the cost. If using the daughters for the model is less costly than the mother then the recursion continues to compare the cost of the hyponyms beneath.

The cost (or description length) for a set of classes is calculated as the model description length (mdl) and the data description length (ddl) [4] :-

$$\begin{array}{cc} mdl & + \, ddl \\ \frac{k}{2} \times \log |TK| & + - \sum_{tk \in TK} \log p(tk) \end{array} \tag{1}$$

k, is the number of WordNet classes being currently considered for the TCM minus one. The MDL method uses the size of TK on the assumption that a larger dataset warrants a more detailed model. The cost of describing the argument head data is calculated using the log of the probability estimate from the classes currently being considered for the model. The probability estimate for a class being considered for the model is calculated using the cumulative frequency of all the hyponym nouns under that class that occur in TK, divided by the number of noun senses that these nouns have, to account for their polysemy. This cumulative frequency is also divided by the total number of noun hyponyms under that class in WordNet to obtain a smoothed estimate for all nouns under the class. The probability of the class is obtained by dividing this frequency estimate by the total frequency of the argument heads. The algorithm is described fully by Li and Abe (1998).

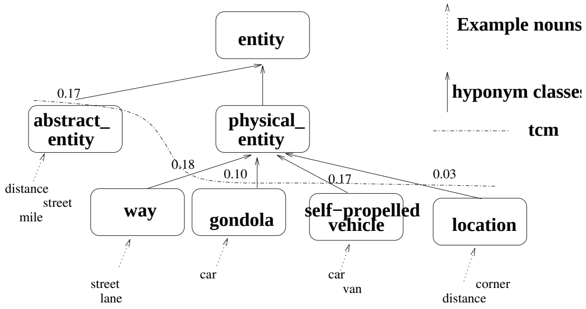

Figure 1: portion of the TCM for the objects of *park*.

A small portion of the TCM for the object slot of *park* is shown in figure 1. WordNet classes are displayed in boxes with a label which best reflects the meaning of the class. The probability estimates are shown for the classes on the TCM. Examples of the argument head data are displayed below the WordNet classes with dotted lines indicating membership at a hyponym class beneath these classes. We cannot show the full TCM due to lack of space, but we show some of the higher probability classes which cover some typical nouns that occur as objects of *park*. Note that probability under the classes **abstract_entity**, **way** and **location** arise because of a systematic parsing error where adverbials such as *distance* in *park illegally some distance from the railway station* are identified by the parser as objects. Systematic noise from the parser has an impact on all the selectional preference models described in this paper.

3.2 WNPROTOs

We propose a method of acquiring selectional preferences which instead of covering all the noun senses in WordNet, just gives a probability distribution over a portion of prototypical classes, we refer to these models as WNPROTOs. A WNPROTO consists of classes within the noun hierarchy which have the highest proportion of word types occurring in the argument head data, rather than using the number of tokens, or frequency, as is used for the TCMs. This allows less frequent, but potentially informative arguments to have some bearing on the models acquired to reduce the impact of highly frequent but polysemous arguments. We then used the frequency data to populate these selected classes.

[4] See (Li and Abe, 1998) for a full explanation.

The classes (C) in the WNPROTO are selected from those which include at least a threshold of 2 argument head types [5] occurring in the training data. Each argument head in the training data is disambiguated according to whichever of the WordNet classes it occurs at or under which has the highest 'type ratio'. Let TY be the set of argument head types in the object slot of the verb for which we are acquiring the preference model. The type ratio for a class (c) is the ratio of noun types ($ty \in TY$) occurring in the training data also listed at or beneath that class in WordNet to the total number of noun types listed at or beneath that particular class in WordNet ($wn_{ty} \in c$). The argument types attested in the training data are divided by the number of WordNet classes that the noun ($classes(ty)$) belongs to, to account for polysemy in the training data.

$$type\ ratio(c) = \frac{\sum_{ty \in TY \in c} \frac{1}{|classes(ty)|}}{|wn_{ty} \in c|} \qquad (2)$$

If more than one class has the same type ratio then the argument is not used for calculating the probability of the preference model. In this way, only arguments that can be disambiguated are used for calculating the probability distribution. The advantage of using the type ratio to determine the classes used to represent the model and to disambiguate the arguments is that it prevents high frequency verb noun combinations from masking the information from prototypical but low frequency arguments. We wish to use classes which are as representative of the argument head types as possible to help detect when an argument head is not related to these classes and is therefore more likely to be non-compositional.

For example, the class **motor_vehicle** is selected for the WNPROTO model of the object slot of *park* even though there are 5 meanings of *car* in WordNet including **elevator_car** and **gondola**. There are 174 occurrences of *car* which overwhelms the frequency of the other objects (e.g. *van* 11, *vehicle* 8) but by looking for classes with a high proportion of types (rather than word tokens) *car* is disambiguated appropriately and the class **motor_vehicle** is selected for representation.

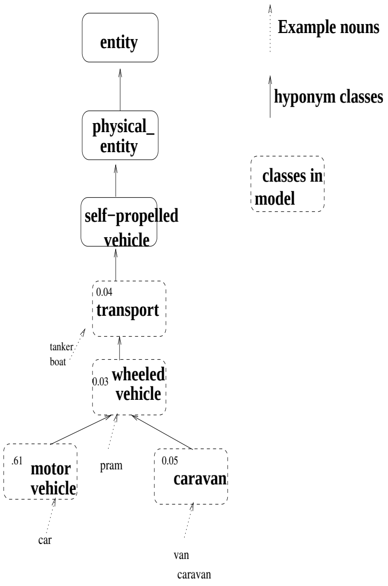

Figure 2: Part of WNPROTO for the object slot of *park*

The relative frequency of each class is obtained from the set of disambiguated argument head tokens and used to provide the probability distribution over this set of classes. Note that in WNPROTO, classes can be subsumed by others in the hyponym hierarchy. The probability assigned to a class is applicable to any descendants in the hyponym hierarchy, except those within any hyponym classes within the WNPROTO. The algorithm for selecting C and calculating the probability distribution is shown as Algorithm 1. Note that we use brackets for comments.

In figure 2 we show a small portion of the WNPROTO for *park*. Again, WordNet classes are displayed in boxes with a label which best reflects the meaning of the class. The probability estimates are shown in the boxes for all the classes included in the WNPROTO. The classes in the WNPROTO model are shown with dashed lines. Examples of the argument head data are displayed below the WordNet classes with dotted lines indicating membership at a hyponym class beneath these classes. We cannot show the full WNPROTO due to lack of space, but we show some of the classes with higher probability which cover some typical nouns that occur as objects of *park*.

[5] We have experimented with a threshold of 3 and obtained similar results.

Algorithm 1 WNPROTO algorithm

```
$C = ()$ {classes in WNPROTO}
$D = ()$ {disambiguated $ty \in TY$}
$fD = 0$ {frequency of disambiguated items}
$TY =$ argument head types {nouns occurring as objects of verb, with associated frequencies}
$C1 \in WordNet$
$where\ |ty \in TY occurring\ in\ c \in C1| > 1$
for all $ty \in TY$ do
    find $c \in classes(ty) \in C1\ where\ c = \text{argmax}_c\ typeratio(c)$
    if $c$ & $c \notin C$ then
        add $c$ to $C$
        add $ty \leftrightarrow c$ to $D$ {Disambiguated $ty$ with $c$}
    end if
end for
for all $c \in C$ do
    if $|ty \leftrightarrow c \in D| > 1$ then
        $fD = fD + frequency(ty)$ {sum frequencies of types under classes to be used in model}
    else
        remove $c$ from $C$ {classes with less than two disambiguated nouns are removed}
    end if
end for
for all $c \in C$ do
    $p(c) = \frac{frequency\text{-}of\text{-}all\text{-}tys\text{-}disambiguated\text{-}to\text{-}class(c,D)}{fD}$ {calculating class probabilities}
end for
```

Algorithm 2 DSPROTO algorithm

```
$C = ()$ {classes in DSPROTO}
$D = ()$ {disambiguated $ty \in TY$}
$fD = 0$ {frequency of disambiguated items}
$TY =$ argument head types {nouns occurring as objects of verb, with associated frequencies}
$C1$ = $cty \in TY\ where\ num\text{-}types\text{-}in\text{-}thesaurus(cty, TY) > 1$
order $C1$ by $num\text{-}types\text{-}in\text{-}thesaurus(cty, TY)$ {classes ordered by coverage of argument head types}
for all $cty \in ordered\, C1$ do
    $Dcty = ()$ {disambiguated for this class}
    for all $ty \in TY where\ in\text{-}thesaurus\text{-}entry(cty, ty)$ do
        if $ty \notin D$ then
            add $ty$ to $Dcty$ {types disambiguated to this class only if not disambiguated by a class used already}
        end if
    end for
    if $|Dcty| > 1$ then
        add $cty$ to $C$
        for all $ty \in Dcty$ do
            add $ty \leftrightarrow cty$ to $D$ {Disambiguated $ty$ with $cty$}
            $fD = fD + frequency(ty)$
        end for
    end if
end for
for all $cty \in C$ do
    $p(cty) = \frac{frequency\text{-}of\text{-}all\text{-}tys\text{-}disambiguated\text{-}to\text{-}class(cty,D)}{fD}$ {calculating class probabilities}
end for
```

3.3 DSPROTOs

We use a thesaurus acquired using the method proposed by Lin (1998). For input we used the grammatical relation data from automatic parses of the BNC. For each noun we considered the co-occurring verbs in the object and subject relation, the modifying nouns in noun-noun relations and the modifying adjectives in adjective-noun relations. Each thesaurus entry consists of the target noun and the 50 most similar nouns, according to Lin's measure of distributional similarity, to the target.

The argument head noun types (TY) are used to find the entries in the thesaurus as the 'classes' (C) of the selectional preference for a given verb. As with WNPROTOs, we only cover argument types which form coherent groups with other argument types since we wish i) to remove noise and ii) to be able to identify argument types which are not related with the other types and therefore may be non-compositional. As our starting point we only consider an argument type as a class for C if its entry in the thesaurus covers at least a threshold of 2 types. [6]

To select C we use a best first search. This method processes each argument type in TY in order of the number of the other argument types from TY that it has in its thesaurus entry of 50 similar nouns. An argument head is selected as a class for C ($cty \in C$) [7] if it covers at least 2 of the argument heads that are not in the thesaurus entries of any of the other classes already selected for C. Each argument head is disambiguated by whichever class in C under which it is listed in the thesaurus and which has the largest number of the TY in its thesaurus entry. When the algorithm finishes processing the ordered argument heads to select C, all argument head types are disambiguated by C apart from those which after disambiguation occur in isolation in a class without other argument types. Finally a probability distribution over C is estimated using the frequency (tokens) of argument types that occur in the thesaurus entries for any $cty \in C$. If an argument type occurs in the entry of more than one cty then it is assigned to whichever of these has the largest number of disambiguated argument head types and its token frequency is attributed to that class. We show the algorithm as Algorithm 2.

class ($p(c)$)	disambiguated objects (freq)
van (0.86)	car (174) van (11) vehicle (8) ...
mile (0.05)	street (5) distance (4) mile (1) ...
yard (0.03)	corner (4) lane (3) door (1)
backside (0.02)	backside (2) bum (1) butt (1) ...

Figure 3: First four classes of DSPROTO model for *park*

The algorithms for WNPROTO algorithm 1 and DSPROTO (algorithm 2) differ because of the nature of the inventories of candidate classes (WordNet and the distributional thesaurus). There are a great many candidate classes in WordNet. The WNPROTO algorithm selects the classes from all those that the argument heads belong to directly and indirectly by looping over all argument types to find the class that disambiguates each by having the largest type ratio calculated using the undisambiguated argument heads. The DSPROTO only selects classes from the fixed set of argument types. The algorithm loops over the argument types with at least two argument heads in the thesaurus entry and ordered by the number of undisambiguated argument heads in the thesaurus entry. This is a best first search to minimise the number of argument heads used in C but maximise the coverage of argument types.

In figure 3, we show part of a DSPROTO model for the object of *park*. [8] Note again that the class **mile** arises because of a systematic parsing error where adverbials such as *distance* in *park illegally some distance from the railway station* are identified by the parser as objects.

4 Experiments

Venkatapathy and Joshi (2005) produced a dataset of verb-object pairs with human judgements of compositionality. They obtained values of r_s between 0.111 and 0.300 by individually applying the 7 features described above in section 2. The best correlation was given by feature 7 and the second best was feature 3. They combined all 7 features using SVMs and splitting their data into test and training data and achieve a r_s of 0.448, which demonstrates

[6] As with the WNPROTOs, we experimented with a value of 3 for this threshold and obtained similar results.

[7] We use cty for the classes of the DSPROTO. These classes are simply groups of nouns which occur under the entry of a noun (ty) in the thesaurus.

[8] We cannot show the full model due to lack of space.

significantly better correlation with the human gold-standard than any of the features in isolation

We evaluated our selectional preference models using the verb-object pairs produced by Venkatapathy and Joshi (2005). [9] This dataset has 765 verb-object collocations which have been given a rating between 1 and 6, by two annotators (both fluent speakers of English). Kendall's Tau (Siegel and Castellan, 1988) was used to measure agreement, and a score of 0.61 was obtained which was highly significant. The ranks of the two annotators gave a Spearman's rank-correlation coefficient (r_s) of 0.71.

The Verb-Object pairs included some adjectives (e.g. *happy, difficult, popular*), pronouns and complements e.g. *become director*. We used the subset of 638 verb-object pairs that involved common nouns in the object relationship since our preference models focused on the object relation for common nouns. For each verb-object pair we used the preference models acquired from the RASP parses of the BNC to obtain the probability of the class that this object occurs under. Where the object noun is a member of several classes ($classes(noun) \in C$) in the model, the class with the largest probability is used. Note though that for WNPROTOs we have the added constraint that a hyponym class from C is selected in preference to a hypernym in C. Compositionality of an object noun and verb is computed as:-

$$comp(noun, verb) = max_{c \in classes(noun) \in C}\ p(c|verb) \quad (3)$$

We use the probability of the class, rather than an estimate of the probability of the object, because we want to determine how likely any word belonging to this class might occur with the given verb, rather than the probability of the specific noun which may be infrequent, yet typical, of the objects that occur with this verb. For example, *convertible* may be an infrequent object of *park*, but it is quite likely given its membership of the class **motor_vehicle**. We do not want to assume anything about the frequency of non-compositional verb-object combinations, just that they are unlikely to be members of classes which represent prototypical objects. We will contrast these models with a baseline frequency feature used by Venkatapathy and Joshi.

method	r_s	$p <$ (one tailed)
selectional preferences		
TCM	0.090	0.0119
WNPROTO	0.223	0.00003
DSPROTO	**0.398**	0.00003
features from V&J		
frequency (f1)	0.141	0.00023
MI (f2)	**0.274**	0.00003
Lin99 (f3)	0.139	0.00023
LSA2 (f7)	0.209	0.00003
combination with SVM		
f2,3,7	0.413	0.00003
f1,2,3,7	0.419	0.00003
DSPROTO f1,2,3,7	**0.454**	0.00003

Table 1: Correlation scores for 638 verb object pairs

We use our selectional preference models to provide the probability that a candidate is representative of the typical objects of the verb. That is, if the object might typically occur in such a relationship then this should lessen the chance that this verb-object combination is non-compositional. We used the probability of the classes from our 3 selectional preference models to rank the pairs and then used Spearman's rank-correlation coefficient (r_s) to compare these ranks with the ranks from the gold-standard.

Our results for the three types of preference models are shown in the first section of table 1. [10] All the correlation values are significant, but we note that using the type based selectional preference models achieves a far greater correlation than using the TCMs. The DSPROTO models achieve the best results which is very encouraging given that they only require raw data and an automatic parser to obtain the grammatical relations.

We applied 4 of the features used by Venkatapathy and Joshi (2005) [11] and described in section 2 to our subset of 638 items. These features were ob-

[9] This verb-object dataset is available from http://www.cis.upenn.edu/~sriramv/mywork.html.

[10] We show absolute values of correlation following (Venkatapathy and Joshi, 2005).

[11] The other 3 features performed less well on this dataset so we do not report the details here. This seems to be because they worked particularly well with the adjective and pronoun data in the full dataset.

tained using the same BNC dataset used by Venkatapathy and Joshi which was obtained using Bikel's parser (Bikel, 2004). We obtained correlation values for these features as shown in table 1 under V&J. These features are feature 1 frequency, feature 2 pointwise mutual information, feature 3 based on (Lin, 1999) and feature 7 LSA feature which considers the similarity of the verb-object pair with the verbal form of the object. Pointwise mutual information did surprisingly well on this 84% subset of the data, however the DSPROTO preferences still outperformed this feature. We combined the DSPROTO and V&J features with an SVM ranking function and used 10 fold cross validation as Venkatapathy and Joshi did. We contrast the result with the V&J features without the preference models. The results in the bottom section of table 1 demonstrate that the preference models can be combined with other features to produce optimal results.

5 Conclusions and Directions for Future Work

We have demonstrated that the selectional preferences of a verbal predicate can be used to indicate if a specific combination with an object is non-compositional. We have shown that selectional preference models which represent prototypical arguments and focus on argument types (rather than tokens) do well at the task. Models produced from distributional thesauruses are the most promising which is encouraging as the technique could be applied to a language without a man-made thesaurus. We find that the probability estimates from our models show a highly significant correlation, and are very promising for detecting non-compositional verb-object pairs, in comparison to individual features used previously.

Further comparison of WNPROTOs and DSPROTOs to other WordNet models are warranted to contrast the effect of our proposal for disambiguation using word types with iterative approaches, particularly those of Clark and Weir (2002). A benefit of the DSPROTOs is that they do not require a hand-crafted inventory. It would also be worthwhile comparing the use of raw data directly, both from the BNC and from google's Web 1T corpus (Brants and Franz, 2006) since web counts have been shown to outperform the Clark and Weir models on a pseudo-disambiguation task (Keller and Lapata, 2003).

We believe that preferences should NOT be used in isolation. Whilst a low preference for a noun may be indicative of peculiar semantics, this may not always be the case, for example *chew the fat*. Certainly it would be worth combining the preferences with other measures, such as syntactic fixedness (Fazly and Stevenson, 2006). We also believe it is worth targeting features to specific types of constructions, for example light verb constructions undoubtedly warrant special treatment (Stevenson et al., 2003)

The selectional preference models we have proposed here might also be applied to other tasks. We hope to use these models in tasks such as diathesis alternation detection (McCarthy, 2000; Tsang and Stevenson, 2004) and contrast with WordNet models previously used for this purpose.

Abstract

Most of the text summarization research carried out to date has been concerned with the summarization of short documents (e.g., news stories, technical reports), and very little work if any has been done on the summarization of very long documents. In this paper, we try to address this gap and explore the problem of book summarization. We introduce a new data set specifically designed for the evaluation of systems for book summarization, and describe summarization techniques that explicitly account for the length of the documents.

1 Introduction

Books represent one of the oldest forms of written communication and have been used since thousands of years ago as a means to store and transmit information. Despite this fact, given that a large fraction of the electronic documents available online and elsewhere consist of short texts such as Web pages, news articles, scientific reports, and others, the focus of natural language processing techniques to date has been on the automation of methods targeting short documents. We are witnessing however a change: an increasingly larger number of books become available in electronic format, in projects such as Gutenberg (http://www.gutenberg.org), Google Book Search (http://books.google.com), or the Million Books project (http://www.archive.org/details/millionbooks). Similarly, a large number of the books published in recent years are often available – for purchase or through libraries – in electronic format. This means that the need for language processing techniques able to handle very large documents such as books is becoming increasingly important.

In this paper, we address the problem of *book summarization*. While there is a significant body of research that has been carried out on the task of text summarization, most of this work has been concerned with the summarization of *short* documents, with a particular focus on news stories. However, books are different in both length and genre, and consequently different summarization techniques are required. In fact, the straight-forward application of a current state-of-the-art summarization tool leads to poor results – a mere 0.348 F-measure compared to the baseline of 0.325 (see the following sections for details). This is not surprising since these systems were developed specifically for the summarization of short news documents.

The paper makes two contributions. First, we introduce a new data set specifically designed for the evaluation of book summaries. We describe the characteristics of a new benchmark consisting of books with manually constructed summaries, and we calculate and provide lower and upper performance bounds on this data set. Second, after briefly describing a summarization system that has been successfully used for the summarization of short documents, we show how techniques that take into account the length of the documents can be used to significantly improve the performance of this system.

2 Related Work

Automatic summarization has received a lot of attention from the natural language processing commu-

Proceedings of the 2007 Joint Conference on Empirical Methods in Natural Language Processing and Computational Natural Language Learning, pp. 380–389, Prague, June 2007. ©2007 Association for Computational Linguistics

nity, ever since the early approaches to automatic abstraction that laid the foundations of the current text summarization techniques (Luhn, 1958; Edmunson, 1969). The literature typically distinguishes between *extraction*, concerned with the identification of the information that is important in the input text; and *abstraction*, which involves a generation step to add fluency to a previously compressed text (Hovy and Lin, 1997). Most of the efforts to date have been concentrated on the extraction step, which is perhaps the most critical component of a successful summarization algorithm, and this is the focus of our current work as well.

To our knowledge, no research work to date was specifically concerned with the automatic summarization of *books*. There is, however, a large and growing body of work concerned with the summarization of short documents, with evaluations typically focusing on news articles. In particular, a significant number of summarization systems have been proposed during the recent Document Understanding Conference exercises (DUC) – annual evaluations that usually draw the participation of 20–30 teams every year.

There are two main trends that can be identified in the summarization literature: *supervised* systems, that rely on machine learning algorithms trained on pre-existing document-summary pairs, and *unsupervised* techniques, based on properties and heuristics derived from the text.

Among the unsupervised techniques, typical summarization methods account for both the weight of the words in sentences, as well as the sentence position inside a document. These techniques have been successfully implemented in the centroid approach (Radev et al., 2004), which extends the idea of *tf.idf* weighting (Salton and Buckley, 1997) by introducing word centroids, as well as integrating other features such as position, first-sentence overlap and sentence length. More recently, graph-based methods that rely on sentence connectivity have also been found successful, using algorithms such as node degree (Salton et al., 1997) or eigenvector centrality (Mihalcea and Tarau, 2004; Erkan and Radev, 2004; Wolf and Gibson, 2004).

In addition to unsupervised methods, supervised machine learning techniques have also been used with considerable success. Assuming the availability of a collection of documents and their corresponding manually constructed summaries, these methods attempt to identify the key properties of a good summary, such as the presence of named entities, positional scores, or the location of key phrases. Such supervised techniques have been successfully used in the systems proposed by e.g. (Teufel and Moens, 1997; Hirao et al., 2002; Zhou and Hovy, 2003; D'Avanzo and Magnini, 2005).

In addition to short news documents, which have been the focus of most of the summarization systems proposed to date, work has been also carried out on the summarization of other types of documents. This includes systems addressing the summarization of e-mail threads (Wan and McKeown, 2004), online discussions (Zhou and Hovy, 2005), spoken dialogue (Galley, 2006), product reviews (Hu and Liu, 2004), movie reviews (Zhuang et al., 2006), or short literary fiction stories (Kazantseva and Szpakowicz, 2006). As mentioned before, we are not aware of any work addressing the task of automatic book summarization.

3 A Data Set for the Evaluation of Book Summarization

A first challenge we encountered when we started working on the task of book summarization was the lack of a suitable data set, designed specifically for the evaluation of summaries of long documents. Unlike the summarization of short documents, which benefits from the data sets made available through the annual DUC evaluations, we are not aware of any publicly available data sets that can be used for the evaluation of methods for book summarization.

The lack of such data sets is perhaps not surprising since even for humans the summarization of books is more difficult and time consuming than the summarization of short news documents. Moreover, books are often available in printed format and are typically protected by copyright laws that do not allow their reproduction in electronic format, which consequently prohibits their public distribution.

We constructed a data set starting from the observation that several English and literature courses make use of books that are sometimes also available in the form of abstracts – meant to ease the access of students to the content of the books. In particular, we have identified two main publishers that make summaries available online for books studied in the U.S. high-school and college systems: Grade Saver (http://www.gradesaver.com) and Cliff's Notes (http://www.cliffsnotes.com/). Fortunately, many of these books are classics that are already in the public domain, and thus for most of them we were able to find the online electronic version of the books on sites such as Gutenberg or Online Literature (http://www.online-literature.com).

For instance, the following is an example drawn from Cliff's Notes summary of *Bleak House* by Charles Dickens.

> On a raw November afternoon, London is enshrouded in heavy fog made harsher by chimney smoke. The fog seems thickest in the vicinity of the High Court of Chancery. The court, now in session, is hearing an aspect of the case of Jarndyce and Jarndyce. A ”little mad old woman” is, as always, one of the spectators. Two ruined men, one a ”sallow prisoner,” the other a man from Shropshire, appear before the court – to no avail. Toward the end of the sitting, the Lord High Chancellor announces that in the morning he will meet with ”the two young people” and decide about making them wards of their cousin....

Starting with the set of books that had a summary available from Cliff's Notes, we removed all the books that did not have an online version, and further eliminated those that did not have a summary available from Grade Saver. This left us with a "gold standard" data set of 50 books, each of them with two manually created summaries.

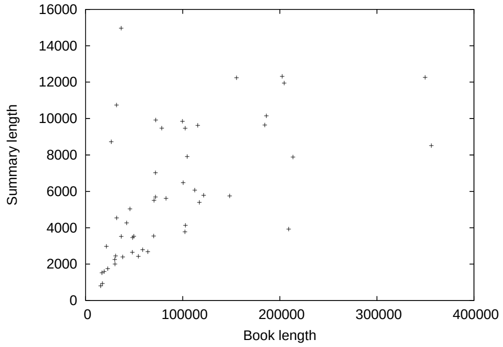

Figure 1: Summary and book lengths for 50 books

The books in this collection have an average length of 92,000 words, with summaries with an average length of 6,500 words (Cliff's Notes) and 7,500 words (Grade Saver). Figure 1 plots the length of the summaries (averaged over the two manual summaries) with respect to the length of the books. As seen in the plot, most of the books have a length of 50,000-150,000 words, with a summary of 2,000–6,000 words, corresponding to a compression rate of about 5-15%. There are also a few very long books, with more than 150,000 words, for which the summaries tend to become correspondingly longer.

3.1 Evaluation Metrics

For the evaluation, we use the ROUGE evaluation toolkit. ROUGE is a method based on Ngram statistics, found to be highly correlated with human evaluations (Lin and Hovy, 2003).[1] Throughout the paper, the evaluations are reported using the ROUGE-1 setting, which seeks unigram matches between the generated and the reference summaries, and which was found to have high correlation with human judgments at a 95% confidence level. Additionally, the final system is also evaluated using the ROUGE-2 (bigram matches) and ROUGE-SU4 (non-contiguous bigrams) settings, which have been frequently used in the DUC evaluations.

In most of the previous summarization evaluations, the data sets were constructed specifically for the purpose of enabling system evaluations, and thus the length of the reference and the generated summaries was established prior to building the data set and prior to the evaluations. For instance, some of the previous DUC evaluations provided reference summaries of 100-word each, and required the participating systems to generate summaries of the same length.

However, in our case we have to deal with pre-existing summaries, with large summary-length variations across the 50 books and across the two reference summaries. To address this problem, we decided to keep one manual summary as the main reference (Grade Saver), and use the other summary (Cliff's Notes) as a way to decide on the length of the generated summaries. This means that for a given book, the Cliff's Notes summary and all the

[1] ROUGE is available at http://haydn.isi.edu/ROUGE/

automatically generated summaries have the same length, and they are all evaluated against the (possibly with a different length) Grade Saver summary. This way, we can also calculate an upper bound by comparing the two manual summaries against each other, and at the same time ensure a fair comparison between the automatically generated summaries and this upper bound.[2]

3.2 Lower and Upper Bounds

To determine the difficulty of the task on the 50 book data set, we calculate and report lower and upper bounds. The lower bound is determined by using a baseline summary constructed by including the first sentences in the book (also known in the literature as the *lead* baseline).[3] As mentioned in the previous section, all the generated summaries – including this baseline – have a length equal to the Cliff's Notes manual summary. The upper bound is calculated by evaluating Cliff's Notes manual summary against the reference Grade Saver summary. Table 1 shows the precision (P), recall (R), and F-measure (F) for these lower and upper bounds, calculated as average across the 50 books.

	P	R	F
Lower bound (lead baseline)	0.380	0.284	0.325
Upper bound (manual summary)	0.569	0.493	0.528

Table 1: Lower and upper bounds for the book summarization task, calculated on the 50 book data set

An automatic system evaluated on this data set is therefore expected to have an F-measure higher than the lower bound of 0.325, and it is unlikely to exceed the upper bound of 0.528 obtained with a human-generated summary.

4 An Initial Summarization System

Our first book summarization experiment was done using a re-implementation of an existing state-of-the-art summarization system. We decided to use the centroid-based method implemented in the MEAD system (Radev et al., 2004), for three main reasons. First, MEAD was shown to lead to good performance in several DUC evaluations, e.g., (Radev et al., 2003; Li et al., 2005). Second, it is an unsupervised method which, unlike supervised approaches, does not require training data (not available in our case). Finally, the centroid-based techniques implemented in MEAD can be optimized and made very efficient, which is an important aspect in the summarization of very long documents such as books.

The latest version of MEAD[4] uses features, classifiers and re-rankers to determine the sentences to include in the summary. The default features are centroid, position and sentence length. The centroid value of a sentence is the sum of the centroid values of the words in the sentence. The centroid value of a word is calculated by multiplying the term frequency (*tf*) of a word by the word's inverse document frequency (*idf*) obtained from the Topic Detection and Tracking (TDT) corpus. The *tf* of a word is calculated by dividing the frequency of a word in a document cluster by the number of documents in the cluster. The positional value P_i of a sentence is calculated using the formula (Radev et al., 2004):

$$P_i = \frac{n - i + 1}{n} * C_{max} \qquad (1)$$

where n represents the number of sentences in the document, i represents the position of the sentence inside the text, and C_{max} is the score of the sentence that has the maximum centroid value.

The summarizer combines these features to give a score to each sentence. The default setting consists of a linear combination of features that assigns equal weights to the centroid and the positional values, and only scores sentences that have more than nine words. After the sentences are scored, the re-rankers are used to modify the scores of a sentence depending on its relation with other sentences. The default re-ranker implemented in MEAD first ranks the sentences by their scores in descending order and iteratively adds the top ranked sentence if the sentence is not *too similar* to the already added sentences. This similarity is computed as a cosine similarity and by default the sentences that exhibit a cosine similarity higher than 0.7 are not added to the

[2] An alternative solution would be to determine the length of the generated summaries using a predefined compression rate (e.g., 10%). However, this again implies great variations across the lengths of the generated versus the manual summaries, which can result in large and difficult to interpret variations across the ROUGE scores.

[3] A second baseline that accounts for text segments is also calculated and reported in section 6.

[4] MEAD 3.11, http://www.summarization.com/mead/

summary. Note that although the MEAD distribution also includes an optional feature calculated using the LexRank graph-based algorithm (Erkan and Radev, 2004), this feature could not be used since it takes days to compute for very long documents such as ours, and thus its application was not tractable.

Although the MEAD system is publicly available for download, in order to be able to make continuous modifications easily and efficiently to the system as we develop new methods, we decided to write our own implementation. Our implementation differs from the original one in certain aspects. First, we determine document frequency counts using the British National Corpus (BNC) rather than the TDT corpus. Second, we normalize the sentence scores by dividing the score of a sentence by the length of the sentence, and instead we eliminate the sentence length feature used by MEAD. Note also that we do not take stop words into account when calculating the length of a sentence. Finally, since we are not doing *multi*-document summarization, we do not use a re-ranker in our implementation.

	P	R	F
MEAD (original download)	0.423	0.296	0.348
MEAD (our implementation)	0.435	0.323	0.369

Table 2: Summarization results using the MEAD system

Table 2 shows the results obtained on the 50 book data set using the original MEAD implementation, as well as our implementation. Although the performance of this system is clearly better than the baseline (see Table 1), it is nonetheless far below the upper bound. In the following section, we explore techniques for improving the quality of the generated summaries by accounting for the length of the documents.

5 Techniques for Book Summarization

We decided to make several changes to our initial system, in order to account for the specifics of the data set we work with. In particular, our data set consists of *very large* documents, and correspondingly the summarization of such documents requires techniques that account for their length.

5.1 Sentence Position In Very Large Documents

The general belief in the text summarization literature (Edmunson, 1969; Mani, 2001) is that the position of sentences in a text represents one of the most important sources of information for a summarization system. In fact, a summary constructed using the lead sentences was often found to be a competitive baseline, with only few systems exceeding this baseline during the recent DUC summarization evaluations.

Although the position of sentences in a document seems like a pertinent heuristic for the summarization of short documents, and in particular for the newswire genre as used in the DUC evaluations, our hypothesis is that this heuristic may not hold for the summarization of very long documents such as books. The style and topic may change several times throughout a book, and thus the leading sentences will not necessarily overlap with the essence of the document.

To test this hypothesis, we modified our initial system so that it does not account for the position of the sentences inside a document, but it only accounts for the weight of the constituent words. Correspondingly, the score of a sentence is determined only as a function of the word centroids, and excludes the positional score. Table 3 shows the average ROUGE scores obtained using the summarization system with and without the position scores.

	P	R	F
With positional scores	0.435	0.323	0.369
Without positional scores	0.459	0.329	0.383

Table 3: Summarization results with and without positional scores

As suspected, removing the position scores leads to a better overall performance, with an increase observed in both the precision and the recall of the system. Although the position in a document is a heuristic that helps the summarization of news stories and other short documents, it appears that the sentences located toward the beginning of a book are not necessarily useful for building the summary of a book.

5.2 Text Segmentation

A major difference between short and long documents stands in the frequent topic shifts typically observed in the later. While short stories are usually concerned with one topic at a time, long documents such as books often cover more than one topic. Thus, the intuition is that a summary should include content covering the important aspects of *all* the topics in the document, as opposed to only generic aspects relevant to the document as a whole. A system for the summarization of *long* documents should therefore extract key concepts from all the topics in the document, and this task is better performed when the topic boundaries are known prior to the summarization step.

To accomplish this, we augment our system with a text segmentation module that attempts to determine the topic shifts, and correspondingly splits the document into smaller segments. Note that although chapter boundaries are available in some of the books in our data set, this is not always the case as there are also books for which the chapters are not explicitly identified. To ensure an uniform treatment of the entire data set, we decided not to use chapter boundaries, and instead apply an automatic text segmentation algorithm.

While several text segmentation systems have been proposed to date, we decided to use a graph-based segmentation algorithm using normalized-cuts (Malioutov and Barzilay, 2006), shown to exceed the performance of alternative segmentation methods. Briefly, the segmentation algorithm starts by modeling the text as a graph, where sentences are represented as nodes in the graph, and inter-sentential similarities are used to draw weighted edges. The similarity between sentences is calculated using cosine similarity, with a smoothing factor that adds the counts of the words in the neighbor sentences. Words are weighted using an adaptation of the *tf.idf* metric, where a document is uniformly split into chunks that are used for the *tf.idf* computation. There are two parameters that have to be set in this algorithm: (1) the length in words of the blocks approximating sentences; and (2) the cut-off value for drawing edges between nodes. Since the method was originally developed for spoken lecture segmentation, we were not able to use the same parameters as suggested in (Malioutov and Barzilay, 2006). Instead, we used a development set of three books, and determined the optimal sentence word-length as 20 and the optimal cut-off value as 25, and these are the values used throughout our experiments.

Once the text is divided into segments, we generate a separate summary for each segment, and consequently create a final summary by collecting sentences from the individual segment summaries in a round-robin fashion. That is, starting with the ranked list of sentences generated by the summarization algorithm for each segment, we pick one sentence at a time from each segment summary until we reach the desired book-summary length.

A useful property of the normalized-cut segmentation algorithm is that one can decide apriori the number of segments to be generated, and so we can evaluate the summarization algorithm for different segmentation granularities. Figure 2 shows the average ROUGE-1 F-measure score obtained for summaries generated using one to 50 segments.

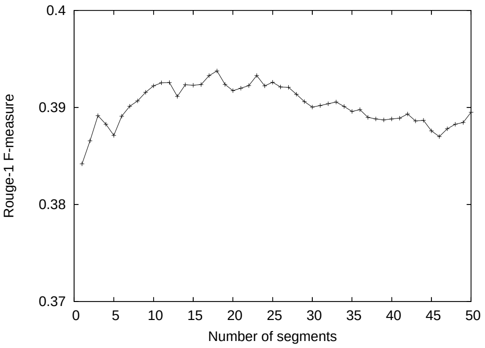

Figure 2: Summarization results for different segmentation granularities.

As seen in the figure, segmenting the text helps the summarization process. The average ROUGE-1 F-measure score raises to more than 0.39 F-measure for increasingly larger number of segments, with a plateau reached at approximately 15–25 segments, followed by a decrease when more than 30 segments are used.

In all the following evaluations, we segment each book into a constant number of 15 segments; in future work, we plan to consider more sophisticated methods for finding the optimal number of segments individually for each book.

5.3 Modified Term Weighting

An interesting characteristic of documents with topic shifts is that words do not have an uniform distribution across the entire document. Instead, their distribution can vary with the topic, and thus the weight of the words should change accordingly.

To account for the distribution of the words inside the entire book, as well as inside the individual topics (segments), we devised a weighting scheme that accounts for four factors: the *segment term frequency (stf)*, calculated as the number of occurrences of a word inside a segment; the *book term frequency (tf)*, determined as the number of occurrences of a word inside a book; the *inverse segment frequency (isf)*, measured as the inverse of the number of segments containing the word; and finally, the *inverse document frequency (idf)*, which takes into account the distribution of a word in a large external corpus (as before, we use the BNC corpus). A word weight is consequently determined by multiplying the book term frequency with the segment term frequency, and the result is then multiplied with the inverse segment frequency and the inverse document frequency. We refer to this weighting scheme as *tf.stf.idf.isf*.

Using this weighting scheme, we prevent a word from having the same score across the entire book, and instead we give a higher weight to its occurrences in segments where the word has a high frequency. For instance, the word *doctor* occurs 30 times in one of the books in our data set, which leads to a constant *tf.idf* score of 36.76 across the entire book. Observing that from these 30 occurrences, 19 appear in just one segment, the *tf.stf.idf.isf* weighting scheme will lead to a weight of 698.49 for that segment, much higher than e.g. the weight of 36 calculated for other segments that have only a few occurrences of this word.

	P	R	F
tf.idf weighting	0.463	0.339	0.391
tf.stf.idf.isf weighting	0.464	0.349	0.398

Table 4: Summarization results using a weighting scheme accounting for the distribution of words inside and across segments

Table 4 shows the summarization results obtained for the new weighting scheme (recall that all the results are calculated for a text segmentation into 15 segments).

5.4 Combining Summarization Methods

The next improvement we made was to bring an additional source of knowledge into the system, by combining the summarization provided by our current system with the summarization obtained from a different method.

We implemented a variation of a centrality graph-based algorithm for unsupervised summarization, which was successfully used in the past for the summarization of short documents. Very briefly, the TextRank system (Mihalcea and Tarau, 2004) – similar in spirit with the concurrently proposed LexRank method (Erkan and Radev, 2004) – works by building a graph representation of the text, where sentences are represented as nodes, and weighted edges are drawn using inter-sentential word overlap. An eigenvector centrality algorithm is then applied on the graph (e.g., PageRank), leading to a ranking over the sentences in the document. An impediment we encountered was the size of the graphs, which become intractably large and dense for very large documents such as books. In our implementation we decided to use a cut-off value for drawing edges between nodes, and consequently removed all the edges between nodes that are farther apart than a given threshold. We use a threshold value of 75, found to work best using the same development set of three books used before.

	P	R	F
Our system	0.464	0.349	0.398
TextRank	0.449	0.356	0.397
COMBINED	0.464	0.363	0.407

Table 5: Summarization results for individual and combined summarization algorithms

Using the same segmentation as before (15 segments), the TextRank method by itself did not lead to improvements over our current centroid-based system. Instead, since we noticed that the summaries generated with our system and with TextRank covered different sentences, we implemented a method that combines the top ranked sentences from the two methods. Specifically, the combination method picks one sentence at a time from the summary generated by our system for each segment, followed by one sentence selected from the summary generated by the TextRank method, and so on. The combination method also specifically avoids redundancy. Table 5 shows the results obtained with our current centroid-based system the TextRank method, as well as the combined method.

5.5 Segment Ranking

In the current system, all the segments identified in a book have equal weight. However, this might not always be the case, as there are sometimes topics inside the book that have higher importance, and which consequently should be more heavily represented in the generated summaries.

To account for this intuition, we implemented a segment ranking method that assigns to each segment a score reflecting its importance inside the book. The ranking is performed with a method similar to TextRank, using a random-walk model over a graph representing segments and segment similarities. The resulting segment scores are multiplied with the sentence scores obtained from the combined method described before, normalized over each segment, resulting in a new set of scores. The top ranked sentences over the entire book are then selected for inclusion in the summary. Table 6 shows the results obtained by using segment ranking.

	P	R	F
COMBINED	0.464	0.363	0.407
COMBINED + Segment Ranking	0.472	0.366	0.412

Table 6: Summarization results using segment ranking

6 Discussion

In addition to the ROUGE-1 metric, the quality of the summaries generated with our final summarization system was also evaluated using the ROUGE-2 and the ROUGE-SU4 metrics, which are frequently used in the DUC evaluations. Table 7 shows the figures obtained with ROUGE-1, ROUGE-2 and ROUGE-SU4 for our final system, for the original MEAD download, as well as for the lower and upper bounds. The table also shows an additional baseline determined by selecting the first sentences in each segment, using the segmentation into 15 segments as determined before. As it can be seen from the F-measure confidence intervals also shown in the table, the improvements obtained by our system with respect to both baselines and with respect to the MEAD system are statistically significant (as the confidence intervals do not overlap).

Upper bound	0.210	0.182	0.195 [0.183,0.206]

Table 7: Evaluation of our final book summarization system using different ROUGE metrics. The table also shows: the lower bound (first sentences in the book); the segment baseline (first sentences in each segment); MEAD (original system download); the upper bound (manual summary). Confidence intervals for F-measure are also included.

Additionally, to determine the robustness of the results with respect to the number of reference summaries, we ran a separate evaluation where both the Grade Saver and the Cliff's Notes summaries were used as reference. As before, the length of the generated summaries was determined based on the Cliff's Notes summary. The F-measure figures obtained in this case using our summarization system were 0.402, 0.057 and 0.127 using ROUGE-1, ROUGE-2 and ROUGE-SU4 respectively. The F-measure figures calculated for the baseline using the first sentences in each segment were 0.340, 0.033 and 0.085. These figures are very close to those listed in Table 7 where only one summary was used as a reference, suggesting that the use of more than one reference summary does not influence the results.

Regardless of the evaluation metric used, the performance of our book summarization system is significantly higher than the one of an existing summarization system that has been designed for the summarization of short documents (MEAD). In fact, if we account for the upper bound of 0.528, the relative error rate reduction for the ROUGE-1 F-measure score obtained by our system with respect to MEAD is a significant 34.44%.

The performance of our system is mainly due to features that account for the length of the document: exclusion of positional scores, text segmentation and segment ranking, and a segment-based weighting scheme. An additional improvement is obtained by combining two different summarization methods. It is also worth noting that our system is efficient, taking about 200 seconds to apply the segmentation algorithm, plus an additional 65 seconds to generate the summary of one book.[5]

To assess the usefulness of our system with respect to the length of the documents, we analyzed the individual results obtained for books of different sizes. Averaging the results obtained for the shorter books in our collection, i.e., 17 books with a length between 20,000 and 50,000 words, the lead baseline gives a ROUGE-1 F-measure score of 0.337, our system leads to 0.378, and the upper bound is measured at 0.498, indicating a relative error rate reduction of 25.46% obtained by our system with respect to the lead baseline (accounting for the maximum achievable score given by the upper bound). Instead, when we consider only the books with a length over 100,000 words (16 books in our data set fall under this category), the lead baseline is determined as 0.347, our system leads to 0.418, and the upper bound is calculated as 0.552, which results in a higher 34.64% relative error rate reduction. This suggests that our system is even more effective for longer books, due perhaps to the features that specifically take into account the length of the books.

There are also cases where our system does not improve over the baseline. For instance, for the summarization of *Candide* by François Voltaire, our system achieves a ROUGE-1 F-measure of 0.361, which is slightly worse than the lead baseline of 0.368. In other cases however, the performance of our system comes close to the upper bound, as it is the case with the summarization of *The House of the Seven Gables* by Nathaniel Hawthorne, which has a lead baseline of 0.296, an upper bound of 0.457, and our system obtains 0.404. This indicates that a possible avenue for future research is to account for the characteristics of a book, and devise summarization methods that can adapt to the specifics of a given book such as length, genre, and others.

7 Conclusions

Although there is a significant body of work that has been carried out on the task of text summarization, most of the research to date has been concerned with the summarization of *short* documents. In this paper, we tried to address this gap and tackled the problem of book summarization.

We believe this paper made two important contributions. First, it introduced a new summarization benchmark, specifically targeting the evaluation of systems for book summarization.[6] Second, it showed that systems developed for the summarization of short documents do not fare well when applied to very long documents such as books, and instead a better performance can be achieved with a system that accounts for the length of the documents. In particular, the book summarization system we developed was found to lead to more than 30% relative error rate reduction with respect to an existing state-of-the-art summarization tool.

Given the increasingly large number of books available in electronic format, and correspondingly the growing need for tools for book summarization, we believe that the topic of automatic book summarization will become increasingly important. We hope that this paper will encourage and facilitate the development of an active line of research concerned with book summarization.

Acknowledgments

The authors are grateful to the Language and Information Technologies research group at the University of North Texas for useful discussions and feedback, and in particular to Carmen Banea for suggesting Cliff's Notes as a source of book summaries. This work was supported in part by a research grant from Google Inc. and by a grant from the Texas Advanced Research Program (#003594).

Abstract

We demonstrate an approach for inducing a tagger for historical languages based on existing resources for their modern varieties. Tags from Present Day English source text are projected to Middle English text using alignments on parallel Biblical text. We explore the use of multiple alignment approaches and a bigram tagger to reduce the noise in the projected tags. Finally, we train a maximum entropy tagger on the output of the bigram tagger on the target Biblical text and test it on tagged Middle English text. This leads to tagging accuracy in the low 80's on Biblical test material and in the 60's on other Middle English material. Our results suggest that our bootstrapping methods have considerable potential, and could be used to semi-automate an approach based on incremental manual annotation.

1 Introduction

Annotated corpora of historical texts provide an important resource for studies of syntactic variation and change in diachronic linguistics. For example, the Penn-Helsinki Parsed Corpus of Middle English (PPCME) (Kroch and Taylor, 2000) has been used to show the existence of syntactic dialectal differences between northern and southern Middle English (Kroch et al., 2000) and to examine the syntactic evolution of the English imperative construction (Han, 2000). However, their utility rests on their having coverage of a significant amount of annotated material from which to draw patterns for such studies, and creating resources such as the PPCME require significant time and cost to produce. Corpus linguists interested in diachronic language studies thus need efficient ways to produce such resources.

One approach to get around the annotation bottleneck is to use semi-automation. For example, when producing part-of-speech tags for the Tycho Brahe corpus of Historical Portuguese (Britto et al., 2002), a set of seed sentences was manually tagged, and the Brill tagger (Brill, 1995) was then trained on those and consequently used to tag other sentences. The output was inspected for errors, the tagger was retrained and used again to tag new sentences, for several iterations.

We also seek to reduce the human effort involved in producing part-of-speech tags for historical corpora. However, our approach does so by leveraging existing resources for a language's modern varieties along with parallel diachronic texts to produce accurate taggers. This general technique has worked well for bilingual bootstrapping of language processing resources for one language based on already available resources from the other. The first to explore the idea were Yarowsky and Ngai (2001), who induced a part-of-speech tagger for French and base noun phrase detectors for French and Chinese via transfer from English resources. They built a highly accurate POS tagger by labeling English text with an existing tagger (trained on English resources), aligning that text with parallel French, projecting the automatically assigned English POS tags across these alignments, and then using the automatically labeled French text to train a new French tagger. This tech-

Proceedings of the 2007 Joint Conference on Empirical Methods in Natural Language Processing and Computational Natural Language Learning, pp. 390–399, Prague, June 2007. ©2007 Association for Computational Linguistics

nique has since been used for other languages and tasks, e.g. morphological analysis (Yarowsky et al., 2001), fine-grained POS tagging for Czech (Drábek and Yarowsky, 2005), and tagging and inducing syntactic dependencies for Polish (Ozdowska, 2006).

This methodology holds great promise for producing tools and annotated corpora for processing diachronically related language pairs, such as Modern English to Middle or Old English. Historical languages suffer from a paucity of machine readable text, inconsistencies in orthography, and grammatical diversity (in the broadest sense possible). This diversity is particularly acute given that diachronic texts of a given language encompass texts and genres spanning across centuries or millenia with a plethora of extra-linguistic influences to complicate the data. Furthermore, even in historically contemporaneous texts, possible dialectal variations further amplify the differences in already idiosyncratic orthographies and syntactic structure.

The present study goes further than Britto et al. (2002) by fully automating the alignment, POS tag induction, and noise elimination process. It is able to utilize the source language to a greater degree than the previously mentioned studies that attempted language neutrality; that is, it directly exploits the genetic similarity between the source and target language. Some amount of surface structural similarity between a diachronic dialect and its derivatives is to be expected, and in the case of Middle English and Modern English, such similarities are not negligible.

The automation process is further aided through the use of two versions of the Bible, which obviates the need for sentence alignment. The modern Bible is tagged using the C&C maximum entropy tagger (Curran and Clark, 2003), and these tags are transferred from source to target through high-confidence alignments aquired from two alignment approaches. A simple bigram tagger is trained from the resulting target texts and then used to relabel the same texts as Middle English training material for the C&C tagger. This tagger utilizes a rich set of features and a wider context, so it can exploit surface similarities between the source and target language. By training it with both the original (Modern English) Penn Treebank Wall Street Journal (WSJ) material and our automatically tagged Middle English Wycliffe material, we achieve an accuracy of 84.8% on predicting coarse tags, improving upon a 63.4% baseline of training C&C on the WSJ sentences alone. Furthermore, we show that the bootstrapped tagger greatly reduces the error rate on out-of-domain, non-Biblical Middle English texts.

2 Data

English provides an ideal test case for our study because of the existence of publically accessible diachronic texts of English and their translations in electronic format and because of the availability of the large, annotated Penn-Helsinki Parsed Corpus of Middle English. The former allows us to create a POS tagger via alignment and projection; the latter allows us to evaluate the tagger on large quantities of human-annotated tags.

2.1 The Bible as a parallel corpus

We take two versions of the Bible as our parallel corpus. For modern English, we utilize the NET Bible[1]. For Middle English (ME), we utilize John Wycliffe's Bible[2]. The first five lines of Genesis in both Bibles are shown in Figure 1.

The Bible offers some advantages beyond its availability. All its translations are numbered, facilitating assessment of accuracy for sentence alignment models. Also, the Bible is quite large for a single text: approximately 950,000 words for Wycliffe's version and 860,000 words for the NET bible. Finally, Wycliffe's Bible was released in the late 14th century, a period when the transition of English from a synthetic to analytical language was finalized. Hence, word order was much closer to Modern English and less flexible than Old English; also, nominal case distinctions were largely neutralized, though some verbal inflections such as distinctions for the first and second person singular in the present tense were still in place (Fennell, 2001). This places Wycliffe's Bible as far back as possible without introducing extreme nominal and verbal inflections in word alignment.

The two Bibles were cleaned and processed for the present task and then examined for levels of correspondence. The two texts were compared for

1 In the beginning God created the heavens and the earth.
2 Now the earth was without shape and empty, and darkness was over the surface of the watery deep, but the Spirit of God was moving over the surface of the water.
3 God said, "Let there be light." And there was light!
4 God saw that the light was good, so God separated the light from the darkness.
5 God called the light day and the darkness night. There was evening, and there was morning, marking the first day.

1 In the bigynnyng God made of nouyt heuene and erthe.
2 Forsothe the erthe was idel and voide, and derknessis weren on the face of depthe; and the Spiryt of the Lord was borun on the watris.
3 And God seide, Liyt be maad, and liyt was maad.
4 And God seiy the liyt, that it was good, and he departide the liyt fro derknessis; and he clepide the liyt,
5 dai, and the derknessis, nyyt. And the euentid and morwetid was maad, o daie.

Figure 1: The first five verses of Genesis the NET Bible (top) and Wycliffe's Bible (below).

whether there were gaps in the chapters and whether one version had more chapters over the other. If discrepancies were found, the non-corresponding chapters were removed. Next, because we assume sentences are already aligned in our approach, discrepancies in verses between the two Bibles were culled. A total of some two hundred lines were removed from both Bibles. This processing resulted in a total of 67 books[3], with 920,000 words for the Wycliffe Bible and 840,000 words for the NET Bible.

2.2 The Penn-Helsinki Parsed Corpus of Middle English

The Penn-Helsinki Parsed Corpus of Middle English is a collection of text samples derived from manuscripts dating 1150–1500 and composed during the same period or earlier. It is based on and expands upon the Diachronic Part of the Helsinki Corpus of English Texts. It contains approximately 1,150,000 words of running text from 55 sources. The texts are provided in three forms: raw, POS tagged, and parsed.

Among the texts included are portions of the Wycliffe Bible. They comprise partial sections of *Genesis* and *Numbers* from the Old Testament and *John I.1–XI.56* from the New Testament. In total, the sections of Wycliffe annotated in PPCME have some 25,000 words in 1,845 sentences. This was used as part of the test material. It is important to note that there are significant spelling differences from the full Wycliffe text that we use for alignment – this is a common issue with early writings that makes building accurate taggers for them more difficult than for the clean and consistent, edited modern texts typically used to evaluate taggers.

2.3 Tagsets

The PPCME uses a part-of-speech tag set that has some differences from that used for the Penn Treebank, on which modern English taggers are generally trained. It has a total of 84 word tags compared to the widely used Penn Treebank tag set's 36 word tags.[4] One of the main reasons for the relative diversity of the PPCME tag set is that it maintains distinctions between the *do*, *have*, and *be* verbs in addition to non-auxiliary verbs. The tag set is further complicated by the fact that composite POS tags are allowed as in *another_D+OTHER*, *midnyght_ADJ+N*, or *armholes_N+NS*.

To measure tagging accuracy, we consider two different tag sets: PTB, and COARSE. A measurement of accuracy is not possible with a direct comparison to the PPMCE tags since our approach la-

[3] 66 books shared by the churches and one book from the Apocrypha. A comparison of the two Bibles revealed that the NET Bible contained the Apocrypha, but only Baruch was shared between the two versions.

[4] In our evaluations, we collapse the many different punctuation tags down to a single tag, $PUNC$.

bels target text in Middle English with tags from the Penn Treebank. Therefore, with PTB, all non-corresponding PPCME tags were conflated if necessary and mapped to the Penn Treebank tag set. Between the two sets, only 8 tags, EX, FW, MD, TO, VB, VBD, VBN, VBP, were found to be fully identical. In cases where tags from the two sets denoted the same category/subcategory, one was simply mapped to the other. When a PPCME tag made finer distinctions than a related Penn tag and could be considered a subcategory of that tag, it was mapped accordingly. For example, the aforementioned auxiliary verb tags in the PPMCE were all mapped to corresponding subcategories of the larger VB tag group, a case in point being the mapping of the perfect participle of *have*_HVN to VBN, a plain verbal participle. For COARSE, the PTB tags were even further reduced to 15 category tags,[5] which is still six more than the core consensus tag set used in Yarkowsky and Ngai (2001). Specifically, COARSE was measured by comparing the first letter of each tag. For example, *NN* and *NNS* are conflated to *N*.

2.4 Penn Treebank Release 3

The POS tagged Wall Street Journal, sections 2 to 21, from the Penn Treebank Release 3 (Marcus et al., 1994) was used to train a Modern English tagger to automatically tag the NET Bible. It was also used to enhance the maximum likelihood estimates of a bigram tagger used to label the target text.

3 Approach

Our approach involves three components: (1) projecting tags from Modern English to Middle English through alignment; (2) training a bigram tagger; and (3) bootstrapping the C&C tagger on Middle English texts tagged by the bigram tagger. This section describes these components in detail.

3.1 Bootstrapping via alignment

Yarowsky and Ngai (2001) were the first to propose the use of parallel texts to bootstrap the creation of taggers. The approach first requires an alignment to be induced between the words of the two texts; tags are then projected from words of the source language to words of the target language. This naturally leads to the introduction of noise in the target language tags. Yarowsky and Ngai deal with this by (a) assuming that each target word can have at most two tags and interpolating the probability of tags given a word between the probabilities of the two most likely tags for that word and (b) interpolating between probabilities for tags projected from 1-to-1 alignments and those from 1-to-n alignments. Each of these interpolated probabilities is parameterized by a single variable; however, Yarowsky and Ngai do not provide details for how the two parameter values were determined/optimized.

Here, we overcome much of the noise by using two alignment approaches, one of which exploits word level similarities (present in genetically derived languages such as Middle English and Present Day English) and builds a bilingual dictionary between them. We also fill in gaps in the alignment by using a bigram tagger that is trained on the noisy tags and then used to relabel the entire target text.

The C&C tagger (Curran and Clark, 2003) was trained on the Wall Street Journal texts in the Penn Treebank and then used to tag the NET Bible (the source text). The POS tags were projected from the source to the Wycliffe Bible based on two alignment approaches, the Dice coefficient and Giza++, as described below.

3.1.1 Dice alignments

A dictionary file is built using the variation of the Dice Coefficient (Dice (1945)) used by Kay and Röscheisen (1993):

$$D(v, w) = \frac{2c}{N_A(v) + N_B(w)} \geq \theta$$

Here, c is the number of cooccurring positions and $N_T(x)$ is the number of occurrences of word x in corpus T. c is calculated only once for redundant occurrences in an aligned sentence pair. For example, it is a given that *the* will generally occur more than once in each aligned sentence. However, even if *the* occurs more than once in each of the sentences in aligned pair s_A and s_B, c is incremented only once. v and w are placed in the word alignment table if they exceed the threshold value θ, which is an empirically determined, heuristic measure.

[5] Namely, adjective, adverb, cardinal number, complementizer/preposition, conjunction, determiner, existential *there*, foreign word, interjection, infinitival *to*, modal, noun, pronoun, verb, and *wh*-words.

The dictionary was structured to establish a surjective relation from the target language to the source language. Therefore, no lexeme in the Wycliffe Bible was matched to more than one lexeme in the NET Bible. The Dice Coefficient was modified so that for a given target word v

$$D_v = \arg\max_w D(v, w)$$

would be mapped to a corresponding word from the source text, such that the Dice Coefficient would be maximized. Dictionary entries were further culled by removing (v, w) pairs whose maximum Dice Coefficient was lower than the θ threshold, for which we used the value 0.5. Finally, each word which had a mapping from the target was sequentially mapped to a majority POS tag. For example, the word *like* which had been assigned four different POS tags, IN, NN, RB, VB, by the C&C tagger in the NET Bible was only mapped to IN since the pairings of the two occurred the most frequently. The result is a mapping from one or more target lexemes to a source lexeme to a majority POS tag. In the case of *like*, two words from the target, *as* and *lijk*, were mapped thereto and to the majority tag IN.

Later, we will refer to the Wycliffe text (partially) labeled with tags projected using the Dice coefficient as DICE_1TO1.

3.1.2 GIZA++ alignments

Giza++ (Och and Ney, 2003) was also used to derive 1-to-n word alignments between the NET Bible and the Wycliffe Bible. This produces a tagged version of the Wycliffe text which we will refer to as GIZA_1TON. In our alignment experiment, we used a combination of IBM Model 1, Model 3, Model 4, and an HMM model in configuring Giza++.

GIZA_1TON was further processed to remove noise from the transferred tag set by creating a 1-to-1 word alignment: each word in the target Middle English text was given its majority tag based on the assignment of tags to GIZA_1TON as a whole. We call this version of the tagged Wycliffe text GIZA_1TO1.

3.2 Bigram tagger

Note that because the projected tags in the Wycliffe materials produced from the alignments are incomplete, there are words in the target text which have no tag. Nonetheless, a bigram tagger can be trained from maximum likelihood estimates for the words and tag sequences which were successfully projected. This serves two functions: (1) it creates a useable bigram tagger and (2) the bigram tagger can be used to fill in the gaps so that the more powerful C&C tagger can be trained on the target text.

A bigram tagger selects the most likely tag sequence T for a word sequence W by:

$$\arg\max_T P(T|W) = P(W|T)P(T)$$

Computing these terms requires knowing the transition probabilities $P(t_i|t_{i-1})$ and the emission probabilities $P(w_i|t_i)$. We use straightforward maximum likelihood estimates from data with projected tags:

$$P(t_i|t_{i-1}) = \frac{f(t_{i-1}, t_i)}{f(t_{i-1})}$$
$$P(w_i|t_i) = \frac{f(w_i, t_i)}{f(t_i)}$$

Estimates for unseen events were obtained through add-one smoothing.

In order to diversify the maximum likelihood estimates and provide robustness against the errors of any one alignment method, we concatenate several tagged versions of the Wycliffe Bible with tags projected from each of our methods (DICE_1TO1, GIZA_1TON, and GIZA_1TO1) and the NET Bible (and its tags from the C&C tagger).

3.3 Training C&C on projected tags

The bigram tagger learned from the aligned text has very limited context and cannot use rich features such as prefixes and suffixes of words in making its predictions. In contrast, the C&C tagger, which is based on that of Ratnaparkhi (1996), utilizes a wide range of features and a larger contextual window including the previous two tags and the two previous and two following words. However, the C&C tagger cannot train on texts which are not fully tagged for POS, so we use the bigram tagger to produce a completely labeled version of the Wycliffe text and train the C&C tagger on this material. The idea is that even though it is training on imperfect material, it will actually be able to correct many errors by virtue of its greater discriminitive power.

	Evaluate on PPCME Wycliffe		Evaluate on PPCME Test	
Model	PTB	COARSE	PTB	COARSE
(a) Baseline, tag NN	9.0	17.7	12.6	20.1
(b) C&C, trained on gold WSJ	56.2	63.4	56.2	62.3
(c) Bigram, trained on DICE_1TO1 and GIZA_1TON	68.0	73.1	43.9	49.8
(d) Bigram, trained on DICE_1TO1 and GIZA_1TO1	74.8	80.5	58.0	63.9
(e) C&C, trained on BOOTSTRAP (920k words)	78.8	84.1	61.3	67.8
(f) C&C, trained on BOOTSTRAP and WSJ and NET	79.5	84.8	61.9	68.5
(g) C&C, trained on (gold) PPCME Wycliffe (25k words)	n/a	n/a	71.0	76.0
(h) C&C, trained on (gold) PPCME training set (327k words)	95.9	96.9	93.7	95.1

Figure 2: Tagging results. See section 4 for discussion.

We will refer to the version of the Wycliffe text (fully) tagged in this way as BOOTSTRAP.

4 Experiments

The M3 and M34 subsections[6] of the Penn Helsinki corpus were chosen for testing since it is not only from the same period as the Wycliffe Bible but since it also includes portions of the Wycliffe Bible. A training set of 14 texts comprising 330,000 words was selected to train the C&C tagger and test the cost necessary to equal or exceed the automatic implementation. The test set consists of 4 texts with 110,000 words. The sample Wycliffe Bible with the gold standard tags has some 25,000 words.

The results of the various configurations are given in Figure 2, and are discussed in detail below.

4.1 Baselines

We provide two baselines. The first is the result of giving every word the common tag NN. The second baseline was established by directly applying the C&C tagger, trained on the Penn Treebank, to the PPCME data. The results are given in lines (a) and (b) of Figure 2 for the first and second baselines, respectively. As can be seen, the use of the Modern English tagger already provides a strong starting point for both evaluation sets.

4.2 Bigram taggers

In section 3.1, we discuss three versions of the Wycliffe target text labeled with tags projected across alignments from the NET Bible. The most straightforward of these were DICE_1TO1 and GIZA_1TON which directly use the alignments from the methods. Training a bigram tagger on these two sources leads to a large improvement over the C&C baseline on the PPCME Wycliffe sentences, as can be seen by comparing line (c) to line (b) in Figure 2. However, performance drops on the PPCME Test sentences, which come from different domains than the bigram tagger's automatically produced Wycliffe training material. This difference is likely to do good estimates of $P(w_i|t_i)$, but poor estimates of $P(t_i|t_{i-1})$ due to the noise introduced in GIZA_1TON.

More conservative tags projection is thus likely to have a large effect on the out-of-domain performance of the learned taggers. To test this, we trained a bigram tagger on DICE_1TO1 and the more conservative GIZA_1TO1 projection. This produces further gains for the PPCME Wycliffe, and enormous improvements on the PPCME Test data (see line (d) of Figure 2). This result confirms that conservativity beats wild guessing (at the risk of reduced coverage) for bootstrapping taggers in this way. This is very much in line with the methodology of Yarowksy and Ngai (2001), who project a small number of tags out of all those predicted by alignment. They achieve this restriction by directly adjusting the probabality mass assigned to projected tags; we do it by using two versions of the target text with tags projected in

[6] Composition dates and manuscript dates for M3 are 1350-1420. The composition dates for M34 are the same but the manuscripts date 1420-1500

two different 1-to-1 ways.

4.3 Bootstrapping the C&C tagger

As described in section 3.3, a bigram tagger trained on DICE_1TO1 and GIZA_1TO1 (i.e., the tagger of line (d)), was used to relabel the entire Wycliffe target text to produce training material for C&C, which we call BOOTSTRAP. The intention is to see whether the more powerful tagger can bootstrap off imperfect tags and take advantage of its richer features to produce a more accurate tagger. As can be seen in row (e) of Figure 2, it provides a 3-4% gain across the board over the bigram tagger which produced its training material (row (d)).

We also considered whether using all available (non-PPCME) training material would improve tagging accuracy by training C&C on BOOTSTRAP, the Modern English Wall Street Journal (from the Penn Treebank), and the automatically tagged NET text[7] It did produce slight gains on both test sets over C&C trained on BOOTSTRAP alone. This is likely due to picking up some words that survived unchanged to the Modern English. Of course, the utility of modern material used directly in this manner will likely vary a great deal depending on the distance between the two language variants. What is perhaps most interesting is that adding the modern material did not *hurt* performance.

4.4 Upperbounds

It is apparent from the results that there is a strong domain effect on the performance of both the bigram and C&C taggers which have been trained on automatically projected tags. There is thus a question of how well we could ever hope to perform on PPCME Test given perfect tags from the Wycliffe texts. To test this, C&C was trained on the *PPCME* version of Wycliffe, which has human annotated standard tags, and then applied on the PPCME test set. We also compare this to training on PPCME texts which are similar to those in PPCME Test.

The results, given in lines (g) and (h) of Figure 2, indicate that there is a likely performance cap on non-Biblical texts when bootstrapping from parallel Biblical texts. The results in line (h) also show that the non-Biblical texts are more difficult, even with gold training material. This is likely due to the wide variety of authors and genres contained in these texts – in a sense, everything is slightly out-of-domain.

4.5 Learning curves with manual annotation

The upperbounds raise two questions. One is whether the performance gap between (g) and (h) in Figure 2 on PPCME Test is influenced by the significant difference in the size of their training sets. The other is how much gold-standard PPCME training material would be needed to match the performance of our best bootstrapped tagger (line (f)). This is a natural question to ask, as it hits at the heart of the utility of our essentially unsupervised approach versus annotating target texts manually.

To examine the cost of manually annotating the target language as compared to our unsupervised method, the C&C tagger was also trained on randomly selected sets of sentences from PPCME (disjoint from PPCME Test). Accuracy was measured on PPCME Wycliffe and Test for a range of training set sizes, sampled at exponentially increasing values (25, 50, 100, . . . , 12800). Though we trained on and predicted the full tagset used by the PPCME, it was evaluated on PTB to give an accurate comparison.[8]

The learning curves on both test sets are shown in Figure 3. The accuracy of the C&C tagger increases rapidly, and the accuracy exceeds our automated method on PPCME Test with just 50 labeled sentences and on the PPCME Wycliffe with 400 examples. This shows the domain of the target text is served much better with the projection approach.

To see how much gold-standard PPCME Wycliffe material is necessary to beat our best bootstrapped tagger, we trained the tagger as in (g) of Figure 2 with varying amounts of material. Roughly 600 labeled sentences were required to beat the performance of 61.9%/68.5% (line (f), on both metrics).

These learning curves suggest that when the domain for which one wishes to produce a tagger is significantly different from the aligned text one has available (in this and in many cases, the Bible), then labeling a small number of examples by hand is a quite reasonable approach (provided random sampling is used). However, if one is not careful, considerable effort could be put into labeling sentences

[7] This essentially is partial self-training since C&C trained on WSJ was used to produce the NET tags.

[8] Evaluation with the full PPCME set produces accuracy figures about 1% lower.

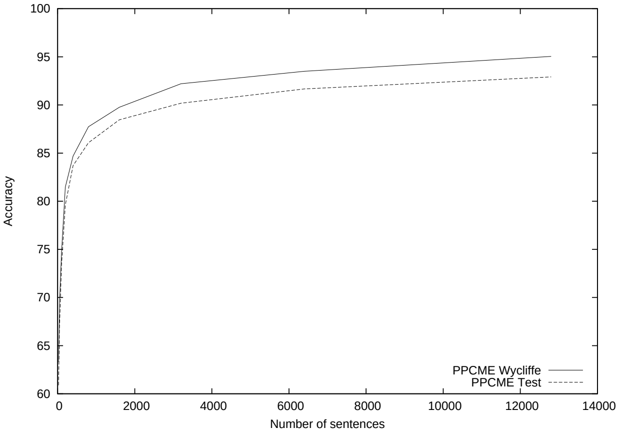

Figure 3: Learning curve showing the accuracy for PTB tags of the C&C tagger on both Bible and Test as it is given more gold-standard PPCME training sentences.

that are not optimal overall (imagine getting unlucky and starting out by manually annotating primarily Wycliffe sentences). The automated methods we present here start producing good taggers immediately, and there is much room for improving them further. Additionally, they could be used to aid manual annotation by proposing high-confidence labels even before any annotation has begun.

5 Related work

Despite the fact that the Bible has been translated into many languages and that it constitutes a solid source for studies in NLP with a concentration on machine translation or parallel text processing, the number of studies involving the Bible is fairly limited. A near exhaustive list is Chew et al.(2006), Melamed(1998), Resnik et al.(1999), and Yarowsky et al.(2001).

Yarowsky and Ngai (2001) is of central relevance to this study. The study describes an unsupervised method for inducing a monolingual POS tagger, base noun-phrase bracketer, named-entity tagger and morphological analyzers from training based on parallel texts, among many of which the Bible was included. This is particularly useful given that no manually annotated data is necessary in the target language and that it works for two languages from different families such as French and Chinese. In the case of POS tagging, only the results for English-French are given and an accuracy of 96% is achieved. Even though this accuracy figure is based on a reduced tag set smaller than the COARSE used in this study, it is still a significant increase over that achieved here. However, their method had the advantage of working in a domain that overlaps with the training data for their POS tagger. Second, the the French tag set utilized in that study is considerably smaller than the Penn Helsinki tag set, a possible source of greater noise due to its size.

Drábek and Yarowsky (2005) create a fine-grained tagger for Czech and French by enriching the tagset for parallel English text with additional morphological information, which, though not directly attested by the impoverished English morphological system (e.g. number on adjectives), typically does appear in other languages.

6 Conclusion

The purpose of the study was to implement a POS tagger for diachronic texts of maximal accuracy with minimal cost in terms of labor, regardless of the shortcuts taken. Such taggers are the building blocks in the design of higher level tools which depend on POS data such as morphological analyzers and parsers, all of which are certain to contribute to diachronic language studies and genetic studies of language change.

We showed that using two conservative methods for projecting tags through alignment significantly improves bigram POS tagging accuracies over a baseline of applying a Modern English tagger to Middle English text. Results were improved further by training a more powerful maximum entropy tagger on the predictions of the bootstrapped bigram tagger, and we observed a further, small boost by using Modern English tagged material in addition to the projected tags when training the maximum entropy tagger.

Nonetheless, our results show that there is still much room for improvement. A manually annotated training set of 400–800 sentences surpassed our best bootstrapped tagger. However, it should be noted that the learning curve approach was based on domain neutral, fully randomized, incremental texts, which are not easily replicated in real world applications. The domain effect is particularly evident in training on the sample Wycliffe and tagging on the test PPCME set. Of course, our approach can be integrated with one based on annotation by using our bootstrapped taggers to perform semi-automated annotation, even *before* the first human-annotated tag has been labeled.

It is not certain how our method would fare on the far more numerous parallel diachronic texts which do not come prealigned. It is also questionable whether it would still be robust on texts predating Middle English, which might as well be written in a foreign language when compared to Modern English. These are all limitations that need to be explored in the future.

Immediate improvements can be sought for the algorithms themselves. By restricting the mapping of words to only one POS tag in the Wycliffe Bible, this seriously handicapped the utility of a bigram tagger. It should be relatively straightforward to transfer the probability mass of multiple POS tags in a modern text to corresponding words in a diachronic text and include this modified probability in the bigram tagger. When further augmented for automatic parameter adjustment with the forward-backward algorithm, accuracy rates might increase further. Furthermore, different algorithms might be better able to take advantage of similarities in orthography and syntactic structure when constructing word alignment tables. Minimum Edit Distance algorithms seem particularly promising in this regard.

Finally, it is evident that the utility of the Bible as a potential resource of parallel texts has largely gone untapped in NLP research. Considering that it has probably been translated into more languages than any other single text, and that this richness of parallelism holds not only for synchrony but diachrony, its usefulness would apply not only to the most immediate concern of building language tools for many of the the world's underdocumented languages, but also to cross-linguistic studies of unprecedented scope at the level of language genera. This study shows that despite the fact that any two Bibles are rarely in a direct parallel relation, standard NLP methods can be applied with success.

Flexible, Corpus-Based Modelling of Human Plausibility Judgements

Abstract

In this paper, we consider the computational modelling of human plausibility judgements for verb-relation-argument triples, a task equivalent to the computation of selectional preferences. Such models have applications both in psycholinguistics and in computational linguistics.

By extending a recent model, we obtain a completely corpus-driven model for this task which achieves significant correlations with human judgements. It rivals or exceeds deeper, resource-driven models while exhibiting higher coverage. Moreover, we show that our model can be combined with deeper models to obtain better predictions than from either model alone.

1 Introduction

One fundamental and intuitive finding in experimental psycholinguistics is that humans judge the plausibility of a verb-argument pair vastly differently depending on the semantic relation in the pair. Table 1 lists example human judgements which McRae et al. (1998) elicited by asking about the plausibility of, e.g., a hunter shooting (relation *agent*) or being shot (relation *patient*). McRae et al. found that "hunter" is judged to be a very plausible *agent* of "shoot" and an implausible *patient*, while the reverse is true for "deer". In linguistics, this phenomenon is explained by *selectional preferences* on verbs' argument positions; we use *plausibility* and *fit with selectional preferences* interchangeably.

Verb	Relation	Noun	Plausibility
shoot	agent	hunter	6.9
shoot	patient	hunter	2.8
shoot	agent	deer	1.0
shoot	patient	deer	6.4

Table 1: Verb-relation-noun triples with plausibility judgements on a 7-point scale (McRae et al., 1998)

In this paper, we consider computational models that predict human plausibility ratings, or the fit of selectional preferences and argument, for such $(verb, relation, argument)$, in short, (v, r, a), triples. Being able to model this type of data is relevant in a number of ways. From the point of view of psycholinguistics, selectional preferences have an important effect in human sentence processing (e.g., McRae et al. (1998), Trueswell et al. (1994)), and models of selectional preferences are therefore necessary to inform models of this process (Padó et al., 2006). In computational linguistics, a multitude of tasks is sensitive to selectional preferences, such as the resolution of ambiguous attachments (Hindle and Rooth, 1993), word sense disambiguation (McCarthy and Carroll, 2003), semantic role labelling (Gildea and Jurafsky, 2002), or testing the applicability of inference rules (Pantel et al., 2007).

A number of approaches has been proposed to model selectional preference data (Padó et al., 2006; Resnik, 1996; Clark and Weir, 2002; Abe and Li, 1996). These models generally operate by generalising from seen (v, r, a) triples to unseen ones. By relying on resources like corpora with semantic role annotation or the WordNet ontology, these models

Proceedings of the 2007 Joint Conference on Empirical Methods in Natural Language Processing and Computational Natural Language Learning, pp. 400–409, Prague, June 2007. ©2007 Association for Computational Linguistics

generally share two problems: (a), limited coverage; and (b), the resource (at least partially) predetermines the generalisations that they can make.

In this paper, we investigate whether it is possible to predict the plausibility of (v, r, a) triples in a completely corpus-driven way. We build on a recent selectional preference model (Erk, 2007) that bases its generalisations on word similarity in a vector space. While that model relies on corpora with semantic role annotation, we show that it is possible to predict plausibility ratings solely on the basis of a parsed corpus, by using shallow cues and a suitable vector space specification.

For evaluation, we use two balanced data sets of human plausibility judgements, i.e., datasets where each verb is paired both with a good agent and a good patient, and where both nouns are presented in either semantic relation (as in Table 1). Using balanced test data is a particularly difficult task, since it forces the models to account reliably both for the influence of the semantic relation (*agent/patient*) and of the argument head ("hunter"/"deer").

We obtain three main results: (a), our model is able to match the superior performance of the model proposed by Padó et al. (2006), while retaining the high coverage of the model proposed by Resnik (1996); (b), using parsing as a preprocessing step improves the model's performance significantly; and (c), a combination of our model with the Padó model exceeds both individual models in accuracy.

Plan of the paper. In Section 2, we give an overview of existing selectional preferences and vector space models. Section 3 introduces our model and discusses its parameters. Sections 4 and 5 present our experimental setup and results. Section 6 concludes.

2 Related Work

Modelling Selectional Preferences with Grammatical Functions. The idea of inducing selectional preferences from corpora was introduced by Resnik (1996). He approximated the semantic verb-argument relations in (v, r, a) triples by grammatical functions, which are readily available for large training corpora. His basic two-step procedure was followed by all later approaches: (1), extract argument headwords for a given predicate and relation from a corpus; (2), generalise to other, similar words using the WordNet noun hierarchy. Other models also relying on the WordNet resource include Abe and Li (1996) and Clark and Weir (2002).

We present Resnik's model in some detail, since we will use it for comparison below. Resnik first computes the overall selectional preference strength for each verb-relation pair, i.e. the degree of "constrainedness" of each relation. This quantity is estimated as the difference (in terms of the Kullback-Leibler divergence D) between the distribution over WordNet argument classes given the relation, $p(c|r)$, and the distribution of argument classes given the current verb-relation combination, $p(c|v, r)$. The intuition is that a verb-relation pair that only allows for a limited range of argument heads will have a probability distribution over argument classes that strongly diverges from the prior distribution.

Next, the selectional association of the triple, $A(v, r, c)$, is computed as the ratio of the selectional preference strength for this particular class, divided by the overall selectional preference strength of the verb-relation pair. This is shown in Equation 1.

$$A(v, r, c) = \frac{p(c|v, r) log \frac{p(c|v,r)}{p(c|r)}}{D(p(c|r)||p(c|v, r))} \qquad (1)$$

Finally, the selectional preference between a verb, a relation, and an argument head is taken to be the selectional association of the verb and relation with the most strongly associated WordNet ancestor class of the argument.

WordNet-based approaches however face two problems. One is a coverage problem due to the limited size of the resource (see the task-based evaluation in Gildea and Jurafsky (2002)). The other is that the shape of the WordNet hierarchy determines the generalisations that the models make. These are not always intuitive. For example, Resnik (1996) observes that $(answer, obj, tragedy)$ receives a high preference because "tragedy" in WordNet is a type of written communication, which is a preferred argument class of "answer".

Rooth et al. (1999) present a fundamentally different approach to selectional preference induction which uses soft clustering to form classes for generalisation and does not take recourse to any hand-crafted resource. We will argue in Section 6 that our model allows more control over the generalisations made.

Modelling Selectional Preferences with Thematic Roles. Padó et al. (2006) present a deeper model for the plausibility of (v, r, a) triples that approximates the relations with thematic roles. It estimates the selectional preferences of a verb-role pair with a generative probability model that equates the plausibility of a (v, r, a) triple with the joint probability of seeing the thematic role with the verb-argument pair. In addition, the model also considers the verb's sense s and the grammatical function gf of the argument; however, since the model is generative, it can make predictions even when not all variables are instantiated. The final model is shown in Equation 2.

$$Plausibility_{v,r,a} = P(v, s, r, a, gf) \tag{2}$$

The induction of this model from the FrameNet corpus of semantically annotated training data (Fillmore et al., 2003) encounters a serious sparse data problem, which is approached by the application of word-class-based and Good-Turing re-estimation smoothing. The resulting model's plausibility predictions are significantly correlated to human judgements, but because of the use of verb-specific thematic roles, the model's coverage is still restricted by the verb coverage of the training corpus.

Vector Space Models. Another class of models that has found wide application in lexical semantics is the family of vector space models. In a vector space model, each *target word* is represented as a vector, typically constructed from co-occurrence counts with context words in a large corpus (the so-called *basis elements*). The underlying assumption is that words with similar meanings occur in similar contexts, and will be assigned similar vectors. Thus, the distance between the vectors of two target words, as given by some distance measure (e.g., Cosine or Jaccard), is a measure of their *semantic similarity*.

Vector space models are simple to construct, and the semantic similarity they provide has found a wide range of applications. Examples in NLP include information retrieval (Salton et al., 1975), automatic thesaurus extraction (Grefenstette, 1994), and predominant sense identification (McCarthy et al., 2004). In cognitive science, they have been used to account for the influence of context on human lexical processing (McDonald and Brew, 2004), and to model lexical priming (Lowe and McDonald, 2000).

A drawback of vector space models is the difficulty of interpreting what some degree of "generic semantic similarity" between two target words means in linguistic terms. In particular, this similarity is not sensitive to selectional preferences over *specific* semantic relations, and thus cannot model the plausibility data we are interested in. The next section demonstrates how the integration of ideas from selectional preference induction makes this distinction possible.

3 The Vector Similarity Model: Corpus-Based Modelling of Plausibility

3.1 Model Architecture

Our model builds on the architecture of Erk (2007). It combines the idea underlying the selectional preference models from Section 2, namely to predict plausibility by generalising over head words, with vector space similarity. The fundamental idea of our model is to model the plausibility of the triple (v, r, a) by comparing the argument head a to other headwords a' which we have already seen in a corpus for the same verb-relation pair (v, r), and which we therefore assume to be plausible. We write $\text{Seen}_r(v)$ for the *set of seen headwords*. Our intuition is that if a is similar to the words in $\text{Seen}_r(v)$, then the triple (v, r, a) is plausible; conversely, if it is very dissimilar, then the triple is implausible.

Concretely, we judge the plausibility of the triple by averaging over the similarity of the vector for a to all vectors for the seen headwords in $\text{Seen}_r(v)$:

$$Pl(v, r, a) = \sum_{a' \in \text{Seen}_r(v)} \frac{w(a') \cdot sim(a, a')}{|\text{Seen}_r(v)|} \tag{3}$$

where w is a weight factor specific to each a'. w can be used to implement different weighting schemes that encode prior knowledge, e.g., about the reliability of different words in $\text{Seen}_r(v)$. In this paper, we only consider a very simple weighting factor, namely the frequency of the seen headwords. This encodes the assumption that similarity to frequent head words is more important than similarity to infrequent ones:

$$Pl(v, r, a) = \sum_{a' \in \text{Seen}_r(v)} \frac{f(a') \cdot sim(a, a')}{|\text{Seen}_r(v)|} \tag{4}$$

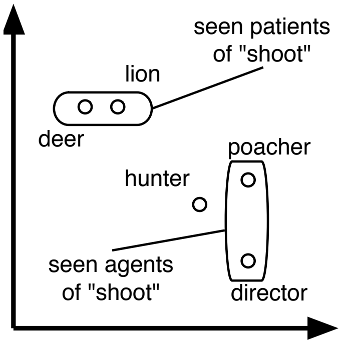

Figure 1: A vector space for estimating the plausibilities of $(shoot, agent, hunter)$ and $(shoot, patient, hunter)$.

This model can be seen as a straightforward implementation of the selectional preference induction process of generalising from seen headwords to other, similar words. By using vector space representations to judge the similarity of words, we obtain a completely corpus-driven model that does not require any additional resources and is very flexible. A complementary view on this model is as a generalisation of traditional vector space models that computes similarity not between two vectors, but between a vector and a set of other vectors. By using the vectors for seen headwords of a given relation as this set, the similarity we compute is specific to this relation.

Example. Figure 1 shows an example vector space. Consider v = “shoot”, r = *agent*, and a = “hunter”. In order to judge whether a hunter is a plausible agent of “shoot”, the vector space representation of “hunter” is compared to all representations of known agents of "shoot”, namely “poacher” and “director”. Due to the nearness of the vector for “hunter” to these two vectors, “hunter” will be judged a fairly good agent of “shoot”. Compare this with the result for the role *patient*: “hunter” is further away from “lion” and “deer”, and will therefore be found to be a rather bad patient of “shoot”. However, “hunter” is still more plausible as a patient of “shoot” than e.g., “director”.

3.2 Instantiating the Model: Unparsed vs. Parsed Corpora

The two major tasks which need to be addressed to obtain an instance of this model are (a), determining the sets of seen head words $\text{Seen}_r(v)$, and (b), the construction of a vector space. Erk (2007) extracted the set of seen head words from corpora with semantic role annotation, and used only a single vector space representation. In this paper, we eliminate the reliance on special annotation by considering shallow approximations of the semantic relations in question. In addition, we discuss in detail which properties of the vector space are crucial for the prediction of plausibility ratings, a much more fine-grained task than the pseudo-word disambiguation task presented in Erk (2007) that is more closely related to semantic role labelling. The goal of our exposition is thus to develop a model that can use more training data, and represent the corpus information optimally in order to obtain superior coverage.

In fact, tasks (a) and (b) can be solved on the basis of unparsed corpora, but we would expect the results to be rather noisy. Fortunately, the state of the art in broad-coverage (Lin, 1993) and unsupervised (Klein and Manning, 2004) dependency parsing allows us to treat dependency parsing merely as a preprocessing step. We therefore describe two instantiations of our model: one based on an unprocessed corpus, and one based on a dependency-based parsed corpus. By comparing the models, we can gauge whether syntactic preprocessing improves model performance. In the following, we describe the strategies the two models adopt for (a) and (b).

Identifying seen head words for relations. Recall that the set $\text{Seen}_r(v)$ is supposed to contain known head words a that are observed in the corpus as triples (v, r, a). In a parsed corpus, we can approximate the relation *agent* by the dependency relation of `subject` provided by the parser, and the relation *patient* by the dependency relation of `object`. In an unparsed corpus, these grammatical relations are unavailable, and the only straightforward evidence we can use is word order. In this case, we assume that words directly adjacent to the left of a predicate are subjects, and therefore *agent*s, whereas words directly to its right are objects, and thus *patient*s.

Vector space topology. The success of our method depends directly on the topology of the vector space. More specifically, two words should only be assigned similar vectors if they are in fact of similar plausibility. If this is not the case, there is no guarantee that a word a that is similar to the words in $\text{Seen}_r(v)$ forms

Target Basis elements	deer	hunter
shoot	10	10
escape	12	12

Target Basis elements	deer	hunter
shoot-SUBJ	0	8
shoot-OBJ	10	2
escape-SUBJ	10	5
escape-OBJ	2	7

Figure 2: Two vector spaces, using as basis elements either context words (above) or words paired with grammatical functions (below)

a plausible triple (v, r, a) itself (cf. Figure 1).

The topology, in turn, is related to the choice of basis elements. Traditional vector space models use context words as basis elements of the space. The top table in Figure 2 illustrates our intuition that such spaces are problematic: “deer” and “hunter” receive identical vectors, even though they show complementary plausibility ratings (cf. Table 1). The reason is that “deer” and “hunter” often co-occur quite closely to one another (e.g., in the vicinity of “shoot”), and thus show a very similar profile in terms of context words. In preliminary experiments, we found that vector spaces with context words as basis elements are in fact unable to distinguish such word pairs reliably.

In contrast, the bottom table in Figure 2 indicates that this problem can be alleviated by using context words *combined with the grammatical relation to the target word* as basis elements. Target words now receive different representations, depending on the grammatical function in which they occur with context words. In consequence, resulting spaces can distinguish, for example, between “hunter” and “deer”.

We adopt word-function pairs as basis elements for the vector spaces in all our models. In a dependency-parsed corpus, the basis elements can be directly read off the syntactic structure. In an unparsed corpus, we again fall back on word order, appending to each context word its relative position to the target word.

4 Experimental Setup

Experimental Materials. In order to make our evaluation comparable to the earlier modelling study by Padó et al. (2006), we present evaluations on the two plausibility judgement datasets used there.[1]

The first dataset consists of 100 data points from McRae et al. (1998). Our example in Table 1, which is taken from this dataset, demonstrates its *balanced* structure: 25 verbs are paired with two arguments and two relations each, such that each argument is highly plausible in one relation, but implausible in the other. The resulting distribution of ratings is thus highly bimodal. Models can only reliably predict the human ratings in this data set if they can capture the difference between verb argument slots as well as as between individual fillers.

The second, larger dataset is less strictly balanced, since its triples are constructed on the basis of corpus co-occurrences (Padó et al., 2006). 18 verbs are combined with the three most frequent subjects and objects from both the Penn Treebank and the FrameNet corpus. Each verb-argument pair was rated both as an agent and as a patient, which leads to a total of 24 rated triples per verb. The dataset contains ratings for a total of 414 triples, due to overlap between corpora. The resulting judgements show a more even distribution of ratings than the McRae data.

Vector Similarity Models. Following our exposition in the last section, we construct two instantiations of our vector similarity model, one using unparsed and one parsed data. Both are trained on the complete British National Corpus (Burnard, 1995, BNC) with more than six million sentences.

The unparsed model (Unparsed) uses the BNC without any pre-processing. We first construct the set of known headwords, $\text{Seen}_r(v)$, as follows: All words up to 2 words to the left of instances of v are assumed to be `subjects`, and thus agents; vice versa for patients to the right. Then, we construct semantic space representations for the experimental arguments and known headwords, adopting optimal parameter settings from the literature (Padó and Lapata, 2007). This means a context window of 5 words to either side and 2,000 basis elements (dimensions), which are formed by the most frequent 1,000 words

[1] We are grateful to Ken McRae for his dataset.

in the BNC, combined with each of the relations agent and patient. All counts are log-likelihood transformed (Lowe, 2001).

To construct the parsed model (Parsed), we dependency-parsed the BNC with Minipar (Lin, 1993). We first obtain the seen headwords $\text{Seen}_r(v)$ by using all subjects and objects of v as agents and patients, respectively. We then construct a vector space for the experimental arguments and known headwords.[2] We use 2,000 dimensions again, but adopt the most frequent $(\mathit{head}, \mathit{grammatical\ function})$ pairs in the BNC as basis elements. The context window is formed by `subject` and `object` dependencies. All counts are log-likelihood transformed.

We experiment with two distance measures to compute vector similarity, namely the Jaccard Coefficient and Cosine Distance, both of which have been shown to yield good performance in NLP tasks (Lee, 1999; McDonald and Lowe, 1998).

Evaluation Procedure. We evaluate our models by correlating the predicted plausibility values with the human judgements, which range between 1 and 7. Since the human judgement data is not normally distributed, we use Spearman's ρ, a non-parametric rank-order test. We determine the statistical significance of differences in correlation strength using the method described in Raghunathan (2003). This method can deal with missing values and thus allows us to compare models with different coverage.

It is difficult to specify a straightforward baseline for our correlation-based evaluation. In contrast to classification tasks, where models choose one out of a fixed number of classes, our model predicts continuous data. This task is more difficult to approximate, e.g., using frequency information.

With respect to upper bounds, we hold that automatic models of plausibility cannot be expected to surpass the typical agreement on the plausibility judgement task between human participants. Thus, we assume an upper bound of $\rho \approx 0.7$.

Comparison against Other Models. We compare our performance to two models from the literature discussed in Section 2. The first model (Pado) is the thematic role-based model by Padó et al. (2006) trained on the FrameNet (Fillmore et al., 2003) release 1.2 example sentences, a subset of the BNC annotated with semantic roles. This corpus contains about 57,000 sentences, which corresponds to roughly 1% of the BNC data.

The second model (Resnik) is the WordNet-based selectional preference model by Resnik (1996), trained on the dependency-parsed BNC (see above).

Model	Coverage	Spearman's ρ
Unparsed Cosine	90%	0.023, ns
Unparsed Jaccard	90%	0.044, ns
Parsed Cosine	91%	0.218, *
Parsed Jaccard	91%	0.129, ns
Resnik	94%	0.028, ns
Pado	56%	0.415, **

Table 2: Model performance on McRae data. *: $p < 0.05$, **: $p < 0.01$

5 Experimental Evaluation

The McRae Dataset. Table 2 summarises our results on the McRae dataset. The upper part shows the results for our two vector similarity models (Parsed/Unparsed), combined with the two distance measures (Cosine/Jaccard). The lower part shows the two resource-based models we use for comparison.

We find that all vector similarity models exhibit high coverage (above 90%), and one model (Parsed Cosine) can predict human judgements with a significant correlation. The instantiation of the model has a significant impact on the performance: The Parsed models clearly outperform the Unparsed models. The effect of the distance measure is less clear-cut, since the Unparsed models perform better with Jaccard, while the Parsed models prefer Cosine.

The deep semantic plausibility model (Pado) makes predictions only for slightly more than half of the data. This low coverage is a direct result of the small overlap in verbs between the McRae dataset and the FrameNet corpus. However, on the data points it covers, it achieves a significant correlation to human judgements. The correlation coefficient is numerically much higher than that of the Parsed Cosine model, but due to the large coverage difference, the two models are not statistically distinguishable.

[2] This space was computed using the `DependencyVectors` software described in Padó and Lapata (2007). This software can be downloaded from `http://www.coli.uni-saarland.de/~pado/dv.html`.

Model	Coverage	Spearman's ρ
Unparsed Cosine	98%	0.117, *
Unparsed Jaccard	98%	0.149, **
Parsed Cosine	98%	0.479, ***
Parsed Jaccard	98%	0.120, *
Resnik	98%	0.237, ***
Pado	97%	0.515, ***

Table 3: Model performance on Pado data. *: $p < 0.05$, **: $p < 0.01$, ***: $p < 0.001$

Resnik's WordNet-based model shows a coverage that is comparable to the vector similarity models, but does not achieve a significant correlation to the human judgements.

The Pado Dataset. Table 3 summarises the results for the Pado dataset. Since all verbs in this dataset are covered in FrameNet, the deep Pado model shows a coverage comparable to all other models, at >95%.

The main difference to the McRae dataset lies in the models' performance. We find that all models, including the Unparsed vector models and Resnik, manage to achieve significant correlations with the human judgements. Within the vector similarity models, the same trends hold as for the McRae dataset: Parsed outperforms Unparsed, and the best combination is Parsed Cosine. The models fall into two clearly separated groups: The Pado and Parsed Cosine models achieve a highly significant correlation, and are statistically indistinguishable. They significantly outperform the second group ($p < 0.001$), formed by all other models. Within this second group, Resnik is numerically the best model and shows a significant correlation with human data; nevertheless, the difference to the first group is evident from its substantially lower correlation coefficient.

The construction of the Pado dataset allows a further analysis. As mentioned in Section 4, the dataset consists of verb-argument pairs drawn from two different corpora. Therefore, each verb is combined both with some arguments that are seen in FrameNet, and some that are not. Our hypothesis is that the FrameNet-trained Pado model performs considerably better on the 216 "FN-Seen" data points (verb-argument pairs observed in FrameNet in at least one relation) than on the 198 "FN-Unseen" data points (verb-argument pairs unseen in both relations).

Table 4 shows the results of this analysis for the best-performing models. We observe a pattern corresponding to our expectations: The performance of the Pado model is clearly worse for FN-Unseen than for FN-Seen, while the Resnik and Parsed Cosine models perform more evenly across both datasets. While the Pado model is significantly better on the FN-Seen dataset, it is numerically outperformed by the Parsed Cosine model for the FN-Unseen data points. We conclude that the deep model is more accurate within the coverage of its resources, but loses its advantage when it has to resort to smoothing.

Model combination. Our last analysis indicates that the models have complementary strengths: the thematic role-based Pado model is the best plausibility predictor on the data points it has seen, while the Parsed cosine model overall predicts human data only numerically worse, and with better coverage. We therefore suggest to combine the predictions of the two models to combine their respective strengths.

For the moment, we only consider a naive backoff scheme: For each data point, we use the prediction of the Pado model if the data point is "FN-Seen" (cf. the last paragraph), and the prediction of the Parsed Cosine model otherwise. Note that this criterion does not consider the predictions of the models themselves, only properties of the underlying training set.

The actual combination requires a normalisation of the respective predictions, since one of the models (Pado) is probabilistic, while the other one (Parsed Cosine) is similarity-based, and their predictions are not directly comparable. We perform a simple normalisation by z-transforming the complete predictions of each model.[3] The combination of the scaled predictions in fact results in an improved correlation with the human data. The correlation coefficient of ρ=0.552 numerically exceeds either base model, and the coverage of 98% corresponds to the coverage of the more robust Parsed Cosine model.

We take this result as evidence that even a simple combination technique can lead to improved predictions. Unfortunately, our naive backoff scheme does not directly carry over to the McRae dataset, where only 2 out of 100 data points are "FN-Seen", and the Pado model would thus hardly contribute.

[3] The z transformation scales a dataset to a mean of 0 and a standard deviation of 1.

Model	FN-Seen Data		FN-Unseen Data	
Parsed Cosine	94%	0.426, ***	100%	0.461, ***
Resnik	96%	0.217, **	100%	0.263, ***
Pado	97%	0.569, ***	96%	0.383, ***

Table 4: Performance on data points seen and unseen in FrameNet (Pado dataset). **: $p < 0.01$ ***: $p < 0.001$

Discussion. We have verified experimentally that our vector similarity model is able to match the performance of a deep plausibility model, exceeding it in coverage, and to outperform a WordNet-based selectional preference model. We conclude that a completely corpus-driven approach constitutes a viable alternative to resource-based models.

One insight from our experiments is that vector similarity models constructed from dependency-parsed corpora perform significantly better than unparsed models. This indicates that dependency relations like `subject` and `object` are reliable syntactic correlates of semantic relations like *agent* and *patient*, but that their approximation in terms of word order introduces considerable noise. The Parsed models are best combined with Cosine Distance. We surmise that Cosine, which tends to consider low-frequency words more than Jaccard, is more susceptible to the additional noise in unparsed corpora.

Furthermore, the choice of basis elements for the vector space is vital: Plausibilities could only be predicted successfully with word-relation pairs as basis elements. This is in contrast to recent results on predominant sense acquisition, the task of identifying the most frequent sense for a given word in an unsupervised manner (McCarthy et al., 2004). On that task, Padó and Lapata (2007) found vector spaces with words as basis elements are in fact competitive with models using word-relation pairs. This divergence underlines an interesting difference between the two tasks. Evidently, predominant senses identification, as a WSD-related task, can succeed on the basis of topical information, which is represented well in word-based spaces. In contrast, plausibility judgments can only be predicted by a space based on word-relation pairs which can represent the finer-grained distinctions arising from different *relations* between verb and noun.

A second important finding is that the relative performance of the different models is the same on the McRae and Pado datasets. The Pado model performs best, followed by our Parsed Cosine vector similarity model, followed by the Unparsed and Resnik models.

The McRae dataset, however, is much more difficult to account for than the Pado data, independent of the model. This effect was already noted by Padó et al. (2006), who attributed it to the very limited overlap between the McRae dataset and FrameNet. While this explanation can account for the difference for the Pado model, we observe the same pattern across all models. This suggests that a more general frequency effect is at work here: The median frequency of the hand-selected McRae nouns is 1,356 in the BNC, as opposed to 8,184 for the corpus-derived Pado nouns. The resulting sparseness affects all model families, since all ultimately rely on co-occurrences.

The performance difference between the two datasets is particularly large for the WordNet-based selectional preference model (Resnik). A further analysis of the model's predictions shows that the model has difficulty in distinguishing between verb-relation-argument triples that differ only in the argument, such as $(shoot, agent, hunter)$ and $(shoot, agent, deer)$. Recall that it is crucial for the prediction of the McRae data to make this distinction, since the arguments for each relation are chosen to differ widely in plausibility. The reason for the Resnik model's difficulty is that arguments are mapped onto WordNet synsets, and whenever two arguments are mapped onto closely related synsets, their plausibility ratings are similar. This problem is graver for the McRae test set, where all arguments are animates, and thus more similar in terms of WordNet, than for the Pado set, which also contains a portion of inanimate arguments with animate counterparts. This analysis highlights again the fundamental problem of resource-based models, where design decisions of the underlying resource may limit, or even mislead, the models' generalisations.

Finally, we have shown in a first experiment that the syntax-based vector similarity model can be combined with the role-base model to obtain a combined model that performs superior to both. In this combined model, the shallow model's better coverage supplements the accurate predictions of the deep model.

6 Conclusions

In this paper, we have considered the computational modelling of human plausibility judgements for verb-relation-argument triples, a task equivalent to the computation of selectional preferences. We have extended a recent proposal (Erk, 2007) which combines ideas from selectional preference induction and vector space models. Our model can be constructed from a large corpus with partial syntactic information (specifically, subject and object relations) from which it builds an optimally informative vector space.

We have demonstrated that the successful evaluation of the model in Erk (2007) on the coarse-grained pseudo-word disambiguation task carries over to the prediction of human plausibility judgments which requires relatively fine-grained, relation-based distinctions. Our model is competitive with existing "deep" models while exhibiting a higher coverage. We have also shown that our vector similarity model can be combined with a "deep" model so that the combined model outperforms both base models. A thorough investigation of strategies for prediction combination and scaling remains future work.

The strategy of our model to derive generalisations directly from corpus data, without recourse to resources, is similar to another family of corpus-driven selectional preference models, namely EM-based clustering models (Rooth et al., 1999). However, we believe that our model has a number of advantages. (1), It is conceptually simple and implements the intuition behind selectional preference models, "generalise from known headwords to unknown ones", particularly directly through the comparison of new headwords to known ones according to a given definition of similarity. (2), The separation of the similarity computation and the acquisition of seen headwords gives the experimenter fine-grained control over the types and sources of information which inform the construction of the model. (3), The instantiation of the similarity computation with a vector space makes it possible to integrate additional linguistic information beyond verb-argument co-occurrences into the model, building on a large body of work in vector space construction. In sum, our modular model provides a higher degree of control than one-step models like the EM-based proposal.

An important avenue of further research is the ability of the vector plausibility model to model finer-grained distinctions between semantic relations beyond the agent/patient dichotomy, as thematic role-based models are able to. Excluding the direct use of role-annotated corpora like FrameNet for coverage reasons, the most promising strategy is to extend our present scheme of approximating semantic relations by grammatical realisations. How much noise this approximation introduces when finer role sets are used is an open research question.

V-Measure: A conditional entropy-based external cluster evaluation measure

Andrew Rosenberg and Julia Hirschberg
Department of Computer Science
Columbia University
New York, NY 10027
{amaxwell,julia}@cs.columbia.edu

Abstract

We present V-measure, an external entropy-based cluster evaluation measure. V-measure provides an elegant solution to many problems that affect previously defined cluster evaluation measures including 1) dependence on clustering algorithm or data set, 2) the "problem of matching", where the clustering of only a portion of data points are evaluated and 3) accurate evaluation and combination of two desirable aspects of clustering, homogeneity and completeness. We compare V-measure to a number of popular cluster evaluation measures and demonstrate that it satisfies several desirable properties of clustering solutions, using simulated clustering results. Finally, we use V-measure to evaluate two clustering tasks: document clustering and pitch accent type clustering.

1 Introduction

Clustering techniques have been used successfully for many natural language processing tasks, such as document clustering (Willett, 1988; Zamir and Etzioni, 1998; Cutting et al., 1992; Vempala and Wang, 2005), word sense disambiguation (Shin and Choi, 2004), semantic role labeling (Baldewein et al., 2004), pitch accent type disambiguation (Levow, 2006). They are particularly appealing for tasks in which there is an abundance of language data available, but manual annotation of this data is very resource-intensive. Unsupervised clustering can eliminate the need for (full) manual annotation of the data into desired classes, but often at the cost of making evaluation of success more difficult.

External evaluation measures for clustering can be applied when class labels for each data point in some evaluation set can be determined *a priori*. The clustering task is then to assign these data points to any number of clusters such that each cluster contains all and only those data points that are members of the same class Given the ground truth class labels, it is trivial to determine whether this perfect clustering has been achieved. However, evaluating how far from perfect an incorrect clustering solution is a more difficult task (Oakes, 1998) and proposed approaches often lack rigor (Meila, 2007).

In this paper, we describe a new entropy-based external cluster evaluation measure, V-MEASURE[1], designed to address the problem of quantifying such imperfection. Like all external measures, V-measure compares a target clustering — e.g., a manually annotated representative subset of the available data — against an automatically generated clustering to determine now similar the two are. We introduce two complementary concepts, completeness and homogeneity, to capture desirable properties in clustering tasks.

In Section 2, we describe V-measure and how it is calculated in terms of homogeneity and completeness. We describe several popular external cluster evaluation measures and draw some comparisons to V-measure in Section 3. In Section 4, we discuss how some desirable properties for clustering are satisfied by V-measure vs. other measures. In Section 5, we present two applications of V-measure, on document clustering and on pitch accent type clustering.

2 V-Measure and Its Calculation

V-measure is an entropy-based measure which explicitly measures how successfully the criteria of homogeneity and completeness have been satisfied. V-measure is computed as the harmonic mean of distinct homogeneity and completeness scores, just as

[1] The 'V' stands for "validity", a common term used to describe the goodness of a clustering solution.

Proceedings of the 2007 Joint Conference on Empirical Methods in Natural Language Processing and Computational Natural Language Learning, pp. 410–420, Prague, June 2007. ©2007 Association for Computational Linguistics

precision and recall are commonly combined into F-measure (Van Rijsbergen, 1979). As F-measure scores can be weighted, V-measure can be weighted to favor the contributions of homogeneity or completeness.

For the purposes of the following discussion, assume a data set comprising N data points, and two partitions of these: a set of classes, $C = \{c_i | i = 1, \ldots, n\}$ and a set of clusters, $K = \{k_i | 1, \ldots, m\}$. Let A be the contingency table produced by the clustering algorithm representing the clustering solution, such that $A = \{a_{ij}\}$ where a_{ij} is the number of data points that are members of class c_i and elements of cluster k_j.

To discuss cluster evaluation measures we introduce two criteria for a clustering solution: homogeneity and completeness. A clustering result satisfies homogeneity if all of its clusters contain only data points which are members of a single class. A clustering result satisfies completeness if all the data points that are members of a given class are elements of the same cluster. The homogenity and completeness of a clustering solution run roughly in opposition: Increasing the homogeneity of a clustering solution often results in decreasing its completeness. Consider, two degenerate clustering solutions. In one, assigning every datapoint into a single cluster, guarantees perfect completeness — all of the data points that are members of the same class are trivially elements of the same cluster. However, this cluster is as *un*homogeneous as possible, since all classes are included in this single cluster. In another solution, assigning each data point to a distinct cluster guarantees perfect homogeneity — each cluster trivially contains only members of a single class. However, in terms of completeness, this solution scores very poorly, unless indeed each class contains only a single member. We define the distance from a perfect clustering is measured as the weighted harmonic mean of measures of homogeneity and completeness.

Homogeneity:

In order to satisfy our homogeneity criteria, a clustering must assign **only** those datapoints that are members of a single class to a single cluster. That is, the class distribution within each cluster should be skewed to a single class, that is, zero entropy. We determine how close a given clustering is to this ideal by examining the conditional entropy of the class distribution given the proposed clustering. In the perfectly homogeneous case, this value, $H(C|K)$, is 0. However, in an imperfect situation, the size of this value, in bits, is dependent on the size of the dataset and the distribution of class sizes. Therefore, instead of taking the raw conditional entropy, we normalize this value by the maximum reduction in entropy the clustering information could provide, specifically, $H(C)$.

Note that $H(C|K)$ is maximal (and equals $H(C)$) when the clustering provides no new information — the class distribution within each cluster is equal to the overall class distribiution. $H(C|K)$ is 0 when each cluster contains only members of a single class, a perfectly homogenous clustering. In the degenerate case where $H(C) = 0$, when there is only a single class, we define homogeneity to be 1. For a perfectly homogenous solution, this normalization, $\frac{H(C|K)}{H(C)}$, equals 0. Thus, to adhere to the convention of 1 being desirable and 0 undesirable, we define homogeneity as:

$$h = \begin{cases} 1 & \text{if } H(C,K) = 0 \\ 1 - \frac{H(C|K)}{H(C)} & \text{else} \end{cases} \tag{1}$$

where

$$\begin{aligned} H(C|K) &= -\sum_{k=1}^{|K|}\sum_{c=1}^{|C|} \frac{a_{ck}}{N} \log \frac{a_{ck}}{\sum_{c=1}^{|C|} a_{ck}} \\ H(C) &= -\sum_{c=1}^{|C|} \frac{\sum_{k=1}^{|K|} a_{ck}}{n} \log \frac{\sum_{k=1}^{|K|} a_{ck}}{n} \end{aligned}$$

Completeness:

Completeness is symmetrical to homogeneity. In order to satisfy the completeness criteria, a clustering must assign **all** of those datapoints that are members of a single class to a single cluster. To evaluate completeness, we examine the distribution of cluster assignments within each class. In a perfectly complete clustering solution, each of these distributions will be completely skewed to a single cluster. We can evaluate this degree of skew by calculating the conditional entropy of the proposed cluster distribution given the class of the component datapoints, $H(K|C)$. In the perfectly complete case, $H(K|C) = 0$. However, in the worst case scenario, each class is represented by every cluster with a distribution equal to the distribution of cluster sizes, $H(K|C)$ is maximal and equals $H(K)$. Finally, in the degenerate case where $H(K) = 0$, when there is a single cluster, we define completeness to be 1. Therefore, symmetric to the calculation above, we define completeness as:

$$c = \begin{cases} 1 & \text{if } H(K,C) = 0 \\ 1 - \frac{H(K|C)}{H(K)} & \text{else} \end{cases} \tag{2}$$

where

$$\begin{aligned} H(K|C) &= -\sum_{c=1}^{|C|}\sum_{k=1}^{|K|} \frac{a_{ck}}{N} \log \frac{a_{ck}}{\sum_{k=1}^{|K|} a_{ck}} \\ H(K) &= -\sum_{k=1}^{|K|} \frac{\sum_{c=1}^{|C|} a_{ck}}{n} \log \frac{\sum_{c=1}^{|C|} a_{ck}}{n} \end{aligned}$$

Based upon these calculations of homogeneity and completeness, we then calculate a clustering solution's V-measure by computing the weighted harmonic mean of homogeneity and completeness, $V_\beta = \frac{(1+\beta)*h*c}{(\beta*h)+c}$. Similarly to the familiar F-measure, if β is greater than 1 completeness is weighted more strongly in the calculation, if β is less than 1, homogeneity is weighted more strongly.

Notice that the computations of homogeneity, completeness and V-measure are completely independent of the number of classes, the number of clusters, the size of the data set and the clustering algorithm used. Thus these measures can be applied to and compared across any clustering solution, regardless of the number of data points (n-invariance), the number of classes or the number of clusters. Moreover, by calculating homogeneity and completeness separately, a more precise evaluation of the performance of the clustering can be obtained.

3 Existing Evaluation Measures

Clustering algorithms divide an input data set into a number of partitions, or clusters. For tasks where some target partition can be defined for testing purposes, we define a "clustering solution" as a mapping from each data point to its cluster assignments in both the target and hypothesized clustering. In the context of this discussion, we will refer to the target partitions, or clusters, as CLASSES, referring only to hypothesized clusters as CLUSTERS.

Two commonly used external measures for assessing clustering success are $Purity$ and $Entropy$ (Zhao and Karypis, 2001), defined as,

$$Purity = \sum_{r=1}^{k} \frac{1}{n} \max_i(n_r^i)$$

$$Entropy = \sum_{r=1}^{k} \frac{n_r}{n}\left(-\frac{1}{\log q} \sum_{i=1}^{q} \frac{n_r^i}{n_r} \log \frac{n_r^i}{n_r}\right)$$

where q is the number of classes, k the number of clusters, n_r is the size of cluster r, and n_r^i is the number of data points in class i clustered in cluster r.

Both these approaches represent plausable ways to evaluate the homogeneity of a clustering solution. However, our completeness criterion is not measured at all. That is, they do not address the question of whether all members of a given class are included in a single cluster. Therefore the $Purity$ and $Entropy$ measures are likely to improve (increased $Purity$, decreased $Entropy$) monotonically with the number of clusters in the result, up to a degenerate maximum where there are as many clusters as data points. However, clustering solutions rated high by either measure may still be far from ideal.

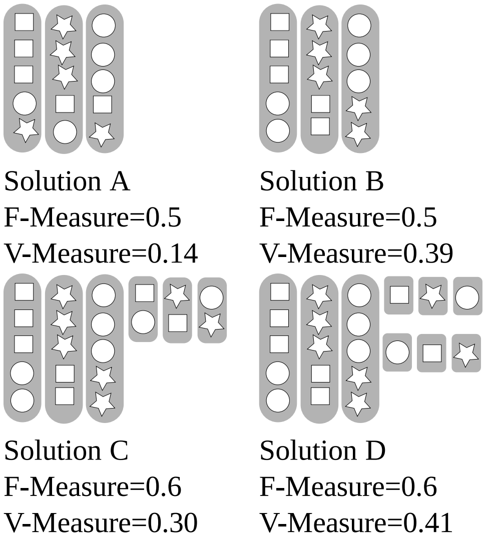
Another frequently used external clustering evaluation measure is commonly refered to as "clustering accuracy". The calculation of this accuracy is inspired by the information retrieval metric of F-Measure (Van Rijsbergen, 1979). The formula for this clustering F-measure as described in (Fung et al., 2003) is shown in Figure 3.

Let N be the number of data points, C the set of classes, K the set of clusters and n_{ij} be the number of members of class $c_i \in C$ that are elements of cluster $k_j \in K$.

$$\begin{aligned} F(C,K) &= \sum_{c_i \in C} \frac{|c_i|}{N} \max_{k_j \in K}\{F(c_i,k_j)\} \qquad (3) \\ F(c_i,k_j) &= \frac{2 * R(c_i,k_j) * P(c_i,k_j)}{R(c_i,k_j) + P(c_i,k_j)} \\ R(c_i,k_j) &= \frac{n_{ij}}{|c_i|} \\ P(c_i,k_j) &= \frac{n_{ij}}{|k_j|} \end{aligned}$$

Figure 1: Calculation of clustering F-measure

This measure has a significant advantage over $Purity$ and $Entropy$, in that it does measure both the homogeneity and the completeness of a clustering solution. Recall is calculated as the portion of items from class i that are present in cluster j, thus measuring how complete cluster j is with respect to class i. Similarly, Precision is calculated as the por-



Solution A
F-Measure=0.5
V-Measure=0.14

Solution B
F-Measure=0.5
V-Measure=0.39

Solution C
F-Measure=0.6
V-Measure=0.30

Solution D
F-Measure=0.6
V-Measure=0.41

Figure 2: Examples of the Problem of Matching

tion of cluster j that is a member of class i, thus measuring how homogenous cluster j is with respect to class i.

Like some other external cluster evaluation techniques (misclassification index (MI) (Zeng et al., 2002), H (Meila and Heckerman, 2001), L (Larsen and Aone, 1999), D (van Dongen, 2000), micro-averaged precision and recall (Dhillon et al., 2003)), F-measure relies on a post-processing step in which each cluster is assigned to a class. These techniques share certain problems. First, they calculate the goodness not only of the given clustering solution, but also of the cluster-class matching. Therefore, in order for the goodness of two clustering solutions to be compared using one these measures, an identical post-processing algorithm must be used. This problem can be trivially addressed by fixing the class-cluster matching function and including it in the definition of the measure as in H. However, a second and more critical problem is the "problem of matching" (Meila, 2007). In calculating the similarity between a hypothesized clustering and a 'true' clustering, these measures only consider the contributions from those clusters that are matched to a target class. This is a major problem, as two significantly different clusterings can result in identical scores.

In figure 2, we present some illustrative examples of the problem of matching. For the purposes of this discussion we will be using F-Measure as the measure to describe the problem of matching, however, these problems affect any measure which requires a mapping from clusters to classes for evaluation.

In the figures, the shaded regions represent CLUSTERS, the shapes represent CLASSES. In a perfect clustering, each shaded region would contain all and only the same shapes. The problem of matching can manifest itself either by not evaluating the entire membership of a cluster, or by not evaluating every cluster. The former situation is presented in the figures A and B in figure 2. The F-Measure of both of these clustering solutions in 0.6. (The precision and recall for each class is $\frac{3}{5}$.) That is, for each class, the best or "matched" cluster contains 3 of 5 elements of the class (Recall) and 3 of 5 elements of the cluster are members of the class (Precision). The make up of the clusters beyond the majority class is not evaluated by F-Measure. Solution B is a better clustering solution than solution A, in terms of both homogeneity (crudely, "each cluster contains fewer[2] classes") and completeness ("each class is contained in fewer clusters"). Indeed, the V-Measure of solution B (0.387) is greater than that of solution A (0.135). Solutions C and D represent a case in which not every cluster is considered in the evaluation of F-Measure. In this example, the F-Measure of both solutions is 0.5 (the harmonic mean of $\frac{3}{5}$ and $\frac{3}{7}$). The small "unmatched" clusters are not measured at all in the calculation of F-Measure. Solution D is a better clustering than solution C – there are no incorrect clusterings of different classes in the small clusters. V-Measure reflects this, solution C has a V-measure of 0.30 while the V-measure of solution D is 0.41.

A second class of clustering evaluation techniques is based on a combinatorial approach which examines the number of pairs of data points that are clustered similarly in the target and hypothesized clustering. That is, each pair of points can either be 1) clustered together in both clusterings (N_{11}), 2) clustered separately in both clusterings (N_{00}), 3) clustered together in the hypothesized but not the target clustering (N_{01}) or 4) clustered together in the target but not in the hypothesized clustering (N_{10}). Based on these 4 values, a number of measures have been proposed, including Rand Index (Rand, 1971),

[2] Homogeneity is not measured by V-measure as a count of the number of classes contained by a cluster but "fewer" is an acceptable way to conceptualize this criterion for the purposes of these examples.

Adjusted Rand Index (Hubert and Arabie, 1985), Γ statistic (Hubert and Schultz, 1976), Jaccard (Milligan et al., 1983), Fowlkes-Mallows (Fowlkes and Mallows, 1983) and Mirkin (Mirkin, 1996). We illustrate this class of measures with the calculation of Rand Index. $Rand(C,K) = \frac{N_{11}+N_{00}}{n(n-1)/2}$ Rand Index can be interpreted as the probability that a pair of points is clustered similarly (together or separately) in C and K.

Meila (2007) describes a number of potential problems of this class of measures posed by (Fowlkes and Mallows, 1983) and (Wallace, 1983). The most basic is that these measures tend not to vary over the interval of $[0,1]$. Transformations like those applied by the adjusted Rand Index and a minor adjustment to the Mirkin measure (see Section 4) can address this problem. However, pair matching measures also suffer from distributional problems. The baseline for Fowlkes-Mallows varies significantly between 0.6 and 0 when the ratio of data points to clusters is greater than 3 — thus including nearly all real-world clustering problems. Similarly, the Adjusted Rand Index, as demonstrated using Monte Carlo simulations in (Fowlkes and Mallows, 1983), varies from 0.5 to 0.95. This variance in the measure's baseline prompts Meila to ask if the assumption of linearity following normalization can be maintained. If the behavior of the measure is so unstable before normalization can users reasonably expect stable behavior **following** normalization?

A final class of cluster evaluation measures are based on information theory. These measures analyze the distribution of class and cluster membership in order to determine how successful a given clustering solution is or how different two partitions of a data set are. We have already examined one member of this class of measures, $Entropy$. From a coding theory perspective, $Entropy$ is the weighted average of the code lengths of each cluster. Our V-measure is a member of this class of clustering measures. One significant advantage that information theoretic evaluation measures have is that they provide an elegant solution to the "problem of matching". By examining the relative sizes of the classes and clusters being evaluated, these measures all evaluate the entire membership of each cluster — not just a 'matched' portion.

Dom's Q_0 measure (Dom, 2001) uses conditional entropy, $H(C|K)$ to calculate the goodness of a clustering solution. That is, given the hypothesized partition, what is the number of bits necessary to represent the true clustering?

However, this term – like the $Purity$ and $Entropy$ measures – only evaluates the homogeneity of a solution. To measure the completeness of the hypothesized clustering, Dom includes a model cost term calculated using a coding theory argument. The overall clustering quality measure presented is the sum of the costs of representing the data ($H(C|K)$) and the model. The motivation for this approach is an appeal to parsimony: Given identical conditional entropies, $H(C|K)$, the clustering solution with the fewest clusters should be preferred. Dom also presents a normalized version of this term, Q_2, which has a range of $(0,1]$ with greater scores being representing more preferred clusterings.

$$Q_0(C,K) = H(C|K) + \frac{1}{n}\sum_{k=1}^{|K|} \log \binom{h(k)+|C|-1}{|C|-1}$$

where C is the target partition, K is the hypothesized partition and $h(k)$ is the size of cluster k.

$$Q_2(C,K) = \frac{\frac{1}{n}\sum_{c=1}^{|C|} \log \binom{h(c)+|C|-1}{|C|-1}}{Q_0(C,K)}$$

We believe that V-measure provides two significant advantages over Q_0 that make it a more useful diagnostic tool. First, Q_0 does not explicitly calculate the degree of completeness of the clustering solution. The cost term captures some of this information, since a partition with fewer clusters is likely to be more complete than a clustering solution with more clusters. However, Q_0 does not explicitly address the interaction between the conditional entropy and the cost of representing the model. While this is an application of the *minimum description length* (MDL) principle (Rissanen, 1978; Rissanen, 1989), it does not provide an intuitive manner for assessing our two competing criteria of homogeneity and completeness. That is, at what point does an increase in conditional entropy (homogeneity) justify a reduction in the number of clusters (completeness).

Another information-based clustering measure is variation of information (VI) (Meila, 2007), $VI(C,K) = H(C|K) + H(K|C)$. VI is presented as a distance measure for comparing partitions (or clusterings) of the same data. It therefore does not distinguish between hypothesized and target clusterings. VI has a number of useful properties. First, it satisfies the metric axioms. This quality allows users to intuitively understand how VI values combine and relate to one another. Secondly, it is "convexly additive". That is to say, if a cluster is split, the distance from the new cluster to the original is the distance induced by the split times the size of the cluster. This property guarantees that all changes to the metric are "local": the impact of splitting or merging clusters is limited to only those clusters involved, and its size is relative to the size of these clusters. Third, VI is n-invariant: the number of data points in the cluster do not affect the value of the measure. VI depends on the relative sizes of the partitions of C and K, not on the number of points in these partitions. However, VI is bounded by the maximum number of clusters in C or K, k^*. Without manual modification however, $k^* = n$, where each cluster contains only a single data point. Thus, while technically n-invariant, the possible values of VI are heavily dependent on the number of data points being clustered. Thus, it is difficult to compare VI values across data sets and clustering algorithms without fixing k^*, as VI will vary over different ranges. It is a trivial modification to modify VI such that it varies over [0,1]. Normalizing, VI by $\log n$ or $1/2 \log k^*$ guarantee this range. However, Meila (2007) raises two potential problems with this modification. The normalization should not be applied if data sets of different sizes are to be compared — it negates the n-invariance of the measure. Additionally, if two authors apply the latter normalization and do not use the same value for k^*, their results will not be comparable.

While VI has a number of very useful distance properties when analyzing a single data set across a number of settings, it has limited utility as a general purpose clustering evaluation metric for use across disparate clusterings of disparate data sets. Our homogeneity (h) and completeness (c) terms both range over [0,1] and are completely n-invariant and k^*-invariant. Furthermore, measuring each as a ratio of bit lengths has greater intuitive appeal than a more opportunistic normalization.

V-measure has another advantage as a clustering evaluation measure over VI and Q_0. By evaluating homogeneity and completeness in a symmetrical, complementary manner, the calculation of V-measure makes their relationship clearly observable. Separate analyses of homogeneity and completeness are not possible with any other cluster evaluation measure. Moreover, by using the harmonic mean to combine homogeneity and completeness, V-measure is unique in that it can also prioritize one criterion over another, depending on the clustering task and goals.

4 Comparing Evaluation Measures

Dom (2001) describes a parametric technique for generating example clustering solutions. He then proceeds to define five "desirable properties" that clustering accuracy measures should display, based on the parameters used to generate the clustering solution. To compare V-measure more directly to alternative clustering measures, we evaluate V-measure and other measures against these and two additional desirable properties.

The parameters used in generating a clustering solution are as follows.

- $|C|$ The number of classes
- $|K|$ The number of clusters
- $|K_{noise}|$ Number of "noise" clusters; $|K_{noise}| < |K|$
- $|C_{noise}|$ Number of "noise" classes; $|C_{noise}| < |C|$
- ϵ Error probability; $\epsilon = \epsilon_1 + \epsilon_2 + \epsilon_3$.
- ϵ_1 The error mass within "useful" class-cluster pairs
- ϵ_2 The error mass within noise clusters
- ϵ_3 The error mass within noise classes

The construction of a clustering solution begins with a matching of "useful" clusters to "useful" classes[3]. There are $|K_u| = |K| - |K_{noise}|$ "useful" clusters and $|C_u| = |C| - |C_{noise}|$ "useful" classes. The claim is useful classes and clusters are matched to each other and matched pairs contain more data points than unmatched pairs. Probability mass of $1 - \epsilon$ is evenly distributed across each match. Error mass of ϵ_1 is evenly distributed across each pair

[3] The operation of this matching is omitted in the interest of space. Interested readers should see (Dom, 2001).

of non-matching useful class/cluster pairs. Noise clusters are those that contain data points equally from each cluster. Error mass of ϵ_2 is distributed across every "noise"-cluster/ "useful"-class pair. We extend the parameterization technique described in (Dom, 2001) in with $|C_{noise}|$ and ϵ_3. Noise classes are those that contain data points equally from each cluster. Error mass of ϵ_3 is distributed across every "useful"-cluster/"noise"-class pair. An example solution, along with its generating parameters is given in Figure 3.

	C_1	C_2	C_3	C_{noise1}
K_1	12	12	2	3
K_2	2	2	12	3
K_{noise1}	4	4	4	0

Figure 3: Sample parametric clustering solution with $n = 60, |K| = 3, |K_{noise}| = 1, |C| = 3, |C_{noise}| = 1, \epsilon_1 = .1, \epsilon_2 = .2, \epsilon_3 = .1$

The desirable properties proposed by Dom are given as P1-P5 in Table 1. We include two additional properties (P6,P7) relating the examined measure value to the number of 'noise' classes and ϵ_3.

P1 For $|K_u| < |C|$ and $\Delta|K_u| \leq (|C| - |K_u|)$, $\frac{\Delta M}{\Delta|K_u|} > 0$

P2 For $|K_u| \geq |C|$, $\frac{\Delta M}{\Delta|K_u|} < 0$

P3 $\frac{\Delta M}{\Delta|K_{noise}|} < 0$, if $\epsilon_2 > 0$

P4 $\frac{\delta M}{\delta\epsilon_1} \leq 0$, with equality only if $|K_u| = 1$

P5 $\frac{\delta M}{\delta\epsilon_2} \leq 0$, with equality only if $|K_{noise}| = 0$

P6 $\frac{\Delta M}{\Delta|C_{noise}|} < 0$, if $\epsilon_3 > 0$

P7 $\frac{\delta M}{\delta\epsilon_3} \leq 0$, with equality only if $|C_{noise}| = 0$

Table 1: Desirable Properties of a cluster evaluation measure M

To evaluate how different clustering measures satisfy each of these properties, we systematically varied each parameter, keeping $|C| = 5$ fixed.

- $|K_u|$: 10 values: 2, 3,. . . , 11
- $|K_{noise}|$: 7 values: 0, 1,. . . , 6
- $|C_{noise}|$: 7 values: 0, 1,. . . , 6
- ϵ_1: 4 values: 0, 0.033, 0.066, 0.1
- ϵ_2: 4 values: 0, 0.066, 0.133, 0.2
- ϵ_3: 4 values: 0, 0.066, 0.133, 0.2

We evaluated the behavior of V-Measure, Rand, Mirkin, Fowlkes-Mallows, Gamma, Jaccard, VI, Q_0, F-Measure against the desirable properties P1-P7[4]. Based on the described systematic modification of each parameter, only V-measure, VI and Q_0 empirically satisfy all of P1-P7 in all experimental conditions. Full results reporting how frequently each evaluated measure satisfied the properties based on these experiments can be found in table 2.

All evaluated measures satisfy P4 and P7. However, Rand, Mirkin, Fowlkes-Mallows, Gamma, Jaccard and F-Measure all fail to satisfy P3 and P6 in at least one experimental configuration. This indicates that the number of 'noise' classes or clusters can be increased without reducing any of these measures. This implies a computational obliviousness to potentially significant aspects of an evaluated clustering solution.

5 Applying V-measure

In this section, we present two clustering experiments. We describe a document clustering experiment and evaluate its results using V-measure, highlighting the interaction between homogeneity and completeness. Second, we present a pitch accent type clustering experiment. We present results from both of these experiments in order to show how V-measure can be used to drawn comparisons across data sets.

5.1 Document Clustering

Clustering techniques have been used widely to sort documents into topic clusters. We reproduce such an experiment here to demonstrate the usefulness of V-measure. Using a subset of the TDT-4 corpus (Strassel and Glenn, 2003) (1884 English news wire and broadcast news documents manually labeled with one of 12 topics), we ran clustering experiments using k-means clustering (McQueen, 1967) and evaluated the results using V-Measure, VI and Q_0 – those measures that satisfied the desirable properties defined in section 4. The topics and relative distributions are as follows: Acts

[4] The inequalities in the desirable properties are inverted in the evaluation of VI, Q_0 and Mirkin as they are defined as distance, as opposed to similarity, measures.

Property	Rand	Mirkin	Fowlkes	Γ	Jaccard	F-measure	Q0	VI	V-Measure
P1	0.18	0.22	1.0	1.0	1.0	1.0	1.0	1.0	1.0
P2	1.0	1.0	0.76	1.0	0.89	0.98	1.0	1.0	1.0
P3	0.0	0.0	0.30	0.19	0.21	0.0	1.0	1.0	1.0
P4	1.0	1.0	1.0	1.0	1.0	1.0	1.0	1.0	1.0
P5	0.50	0.57	1.0	1.0	1.0	1.0	1.0	1.0	1.0
P6	0.20	0.20	0.41	0.26	0.52	0.87	1.0	1.0	1.0
P7	1.0	1.0	1.0	1.0	1.0	1.0	1.0	1.0	1.0

Table 2: Rates of satisfaction of desirable properties

of Violence/War (22.3%), Elections (14.4%), Diplomatic Meetings (12.9%), Accidents (8.75%), Natural Disasters (7.4%), Human Interest (6.7%), Scandals (6.5%), Legal Cases (6.4%), Miscellaneous (5.3%), Sports (4.7), New Laws (3.2%), Science and Discovery (1.4%).

We employed stemmed (Porter, 1980), tf*idf-weighted term vectors extracted for each document as the clustering space for these experiments, which yielded a very high dimension space. To reduce this dimensionality, we performed a simple feature selection procedure including in the feature vector only those terms that represented the highest tf*idf value for at least one data point. This resulted in a feature vector containing 484 tf*idf values for each document. Results from k-means clustering are are shown in Figure 4.

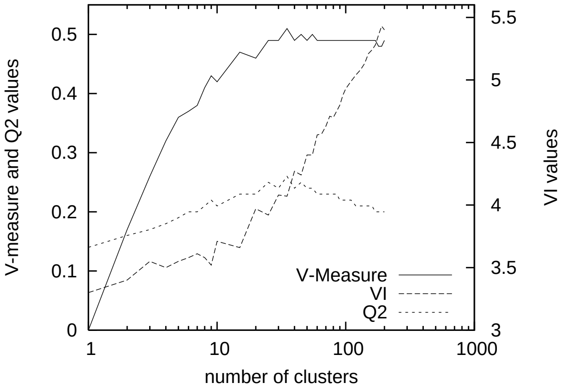


Figure 4: Results of document clustering measured by V-Measure, VI and Q_2

The first observation that can be drawn from these results is the degree to which VI is dependent on the number of clusters (k). This dependency severely limits the usefulness of VI: it is inappropriate in selecting an appropriate parameter for k or for evaluating the distance between clustering solutions generated using different values of k.

V-measure and Q_2 demonstrate similar behavior in evaluating these experimental results. They both reach a maximal value with 35 clusters, however, Q_2 shows a greater descent as the number of clusters increases. We will discuss this quality in greater detail in section 5.2.

5.2 Pitch Accent Clustering

Pitch accent is how speakers of many languages make a word intonational prominent. In most pitch accent languages, words can also be accented in different ways to convey different meanings (Hirschberg, 2002). In the ToBI labeling conventions for Standard American English (Silverman et al., 1992), for example, there are five different accent types (H*, L*, H+!H*, L+H*, L*+H).

We extracted a number of acoustic features from accented words within the read portion of the Boston Directions Corpus (BDC) (Nakatani et al., 1995) and examined how well clustering in these acoustic dimensions correlates to manually annotated pitch accent types. We obtained a very skewed distribution, with a majority of H* pitch accents.[5] We therefore included only a randomly selected 10% sample of H* accents, providing a more even distribution of pitch accent types for clustering: H* (54.4%), L*(32.1%), L+H* (26.5%), L*+H (2.8%), H+!H* (2.1%).

We extracted ten acoustic features from each accented word to serve as the clustering space for this experiment. Using Praat's (Boersma, 2001) Get Pitch (ac)... function, we calculated the mean F0 and ΔF0, as well as z-score speaker normalized versions of the same. We included in the feature vector the relative location of the maximum pitch value in the word as well as the distance between this max-

[5] Pitch accents containing a high tone may also be downstepped, or spoken in a compressed pitch range. Here we collapsed all DOWNSTEPPED instances of each pitch accent with the corresponding non-downstepped instances.

imum and the point of maximum intensity. Finally, we calculated the raw and speaker normalized slope from the start of the word to the maximum pitch, and from the maximum pitch to the end of the word.

Using this feature vector, we performed k-means clustering and evaluate how successfully these dimensions represent differences between pitch accent types. The resulting V-measure, VI and Q_0 calculations are shown in Figure 5.

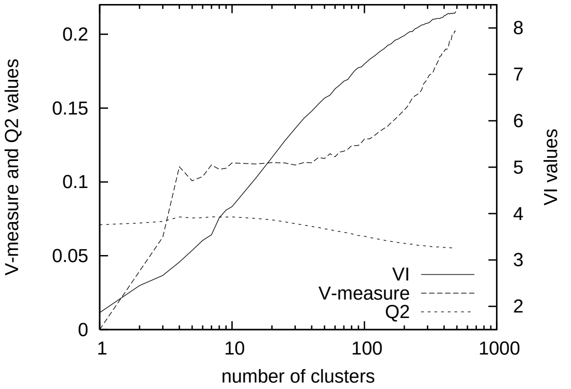

Figure 5: Results of pitch accent clustering measured by V-Measure, VI and Q_0

In evaluating the results from these experiments, Q_2 and V-measure reveal considerably different behaviors. Q_2 shows a maximum at $k = 10$, and descends at k increases. This is an artifact of the MDL principle. Q_2 makes the claim that a clustering solution based on fewer clusters is preferable to one using more clusters, and that the balance between the number of clusters and the conditional entropy, $H(C|K)$, should be measured in terms of coding length. With V-measure, we present a different argument. We contend that the a high value of k does not inherently reduce the goodness of a clustering solution. Using these results as an example, we find that at approximately 30 clusters an increase of clusters translates to an increase in V-Measure. This is due to an increased homogeneity ($\frac{H(C|K)}{H(C)}$) and a relatively stable completeness ($\frac{H(K|C)}{H(K)}$). That is, inclusion of more clusters leads to clusters with a more skewed within-cluster distribution and a equivalent distribution of cluster memberships within classes. This is intuitively preferable – one criterion is improved, the other is not reduced – despite requiring additional clusters. This is an instance in which the *MDL* principle limits the usefulness of Q_2. We again (see section 5.1) observe the close dependency of VI and k. Moreover, in considering figures 5 and 4, simultaneously, we see considerably higher values achieved by the document clustering experiments. Given the naïve approaches taken in these experiments, this is expected – and even desired – given the previous work on these tasks: document clustering has been notably more successfully applied than pitch accent clustering. These examples allow us to observe how transparently V-measure can be used to compare the behavior across distinct data sets.

6 Conclusion

We have presented a new external cluster evaluation measure, V-measure, and compared it with existing clustering evaluation measures. V-measure is based upon two criteria for clustering usefulness, homogeneity and completeness, which capture a clustering solution's success in including all and only datapoints from a given class in a given cluster. We have also demonstrated V-measure's usefulness in comparing clustering success across different domains by evaluating document and pitch accent clustering solutions. We believe that V-measure addresses some of the problems that affect other cluster measures. 1) It evaluates a clustering solution independent of the clustering algorithm, size of the data set, number of classes and number of clusters. 2) It does not require its user to map each cluster to a class. Therefore, it only evaluates the quality of the clustering, not a post-hoc class-cluster mapping. 3) It evaluates the clustering of every data point, avoiding the "problem of matching". 4) By evaluating the criteria of both homogeneity and completeness, V-measure is more comprehensive than those that evaluate only one. 5) Moreover, by evaluating these criteria separately and explicitly, V-measure can serve as an elegant diagnositic tool providing greater insight into clustering behavior.

Abstract

In this paper, we proposed a novel probabilistic generative model to deal with explicit multiple-topic documents: Parametric Dirichlet Mixture Model(PDMM). PDMM is an expansion of an existing probabilistic generative model: Parametric Mixture Model(PMM) by hierarchical Bayes model. PMM models multiple-topic documents by mixing model parameters of each single topic with an equal mixture ratio. PDMM models multiple-topic documents by mixing model parameters of each single topic with mixture ratio following Dirichlet distribution. We evaluate PDMM and PMM by comparing F-measures using MEDLINE corpus. The evaluation showed that PDMM is more effective than PMM.

1 Introduction

Documents, such as those seen on Wikipedia and Folksonomy, have tended to be assigned with explicit multiple topics. In this situation, it is important to analyze a linguistic relationship between documents and the assigned multiple topics . We attempt to model this relationship with a probabilistic generative model. A probabilistic generative model for documents with multiple topics is a probability model of the process of generating documents with multiple topics. By focusing on modeling the generation process of documents and the assigned multiple topics, we can extract specific properties of documents and the assigned multiple topics. The model can also be applied to a wide range of applications such as automatic categorization for multiple topics, keyword extraction and measuring document similarity, for example.

A probabilistic generative model for documents with multiple topics is categorized into the following two models. One model assumes a topic as a latent topic. We call this model the latent-topic model. The other model assumes a topic as an explicit topic. We call this model the explicit-topic model.

In a latent-topic model, a latent topic indicates not a concrete topic but an underlying implicit topic of documents. Obviously this model uses an unsupervised learning algorithm. Representative examples of this kind of model are Latent Dirichlet Allocation(LDA)(D.M.Blei et al., 2001; D.M.Blei et al., 2003) and Hierarchical Dirichlet Process(HDP)(Y.W.Teh et al., 2003).

In an explicit-topic model, an explicit topic indicates a concrete topic such as economy or sports, for example. A learning algorithm for this model is a supervised learning algorithm. That is, an explicit topic model learns model parameter using a training data set of tuples such as (documents, topics). Representative examples of this model are Parametric Mixture Models(PMM1 and PMM2)(Ueda, N. and Saito, K., 2002a; Ueda, N. and Saito, K., 2002b). In the remainder of this paper, PMM indicates PMM1 because PMM1 is more effective than PMM2.

In this paper, we focus on the explicit topic model. In particular, we propose a novel model that is based on PMM but fundamentally improved.

The remaining part of this paper is organized as follows. Sections 2 explains terminology used in the

Proceedings of the 2007 Joint Conference on Empirical Methods in Natural Language Processing and Computational Natural Language Learning, pp. 421–429, Prague, June 2007. ©2007 Association for Computational Linguistics

following sections. Section 3 explains PMM that is most directly related to our work. Section 4 points out the problem of PMM and introduces our new model. Section 5 evaluates our new model. Section 6 summarizes our work.

2 Terminology

This section explains terminology used in this paper. K is the number of explicit topics. V is the number of words in the vocabulary. $\mathscr{V} = \{1, 2, \cdots, V\}$ is a set of vocabulary index. $\mathscr{Y} = \{1, 2, \cdots, K\}$ is a set of topic index. N is the number of words in a document. $\boldsymbol{w} = (w_1, w_2, \cdots, w_N)$ is a sequence of N words where w_n denotes the nth word in the sequence. $\boldsymbol{w}$ is a document itself and is called words vector. $\boldsymbol{x} = (x_1, x_2, \cdots, x_V)$ is a word-frequency vector, that is, BOW(Bag Of Words) representation where x_v denotes the frequency of word v. w_n^v takes a value of 1(0) when w_n is $v \in \mathscr{V}$ (is not $v \in \mathscr{V}$). $\boldsymbol{y} = (y_1, y_2, \cdots, y_K)$ is a topic vector into which a document $\boldsymbol{w}$ is categorized, where y_i takes a value of 1(0) when the ith topic is (not) assigned with a document $\boldsymbol{w}$. $I_y \subset \mathscr{Y}$ is a set of topic index i, where y_i takes a value of 1 in $\boldsymbol{y}$. $\sum_{i \in I_y}$ and $\Pi_{i \in I_y}$ denote the sum and product for all i in I_y, respectively. $\Gamma(x)$ is the Gamma function and Ψ is the Psi function(Minka, 2002). A probabilistic generative model for documents with multiple topics models a probability of generating a document $\boldsymbol{w}$ in multiple topics $\boldsymbol{y}$ using model parameter Θ, i.e., models $P(\boldsymbol{w}|\boldsymbol{y}, \Theta)$. A multiple categorization problem is to estimate multiple topics $\boldsymbol{y}^*$ of a document $\boldsymbol{w}^*$ whose topics are unknown. The model parameters are learned by documents $D = \{(\boldsymbol{w_d}, \boldsymbol{y_d})\}_{d=1}^M$, where M is the number of documents.

3 Parametric Mixture Model

In this section, we briefly explain Parametric Mixture Model(PMM)(Ueda, N. and Saito, K., 2002a; Ueda, N. and Saito, K., 2002b).

3.1 Overview

PMM models multiple-topic documents by mixing model parameters of each single topic with an equal mixture ratio, where the model parameter θ_{iv} is the probability that word v is generated from topic i. This is because it is impractical to use model parameter corresponding to multiple topics whose number is $2^K - 1$(all combination of K topics). PMM achieved more useful results than machine learning methods such as Naive Bayes, SVM, K-NN and Neural Networks (Ueda, N. and Saito, K., 2002a; Ueda, N. and Saito, K., 2002b).

3.2 Formulation

PMM employs a BOW representation and is formulated as follows.

$$P(\boldsymbol{w}|\boldsymbol{y}, \boldsymbol{\theta}) = \Pi_{v=1}^{V} (\varphi(v, \boldsymbol{y}, \boldsymbol{\theta}))^{x_v} \tag{1}$$

$\boldsymbol{\theta}$ is a $K \times V$ matrix whose element is $\theta_{iv} = P(v|y_i = 1)$. $\varphi(v, \boldsymbol{y}, \boldsymbol{\theta})$ is the probability that word v is generated from multiple topics $\boldsymbol{y}$ and is defined as the linear sum of $h_i(\boldsymbol{y})$ and θ_{iv} as follows: $\varphi(v, \boldsymbol{y}, \boldsymbol{\theta}) = \sum_{i=1}^K h_i(\boldsymbol{y})\theta_{iv}$

$h_i(\boldsymbol{y})$ is a mixture ratio corresponding to topic i and is formulated as follows:

$$h_i(\boldsymbol{y}) = \frac{y_i}{\sum_{j=1}^K y_j}, \sum_{i=1}^K h_i(\boldsymbol{y}) = 1.$$
$$\text{(if } y_i = 0\text{, then } h_i(\boldsymbol{y}) = 0)$$

3.3 Learning Algorithm of Model Parameter

The learning algorithm of model parameter $\boldsymbol{\theta}$ in PMM is an iteration method similar to the EM algorithm. Model parameter $\boldsymbol{\theta}$ is estimated by maximizing $\Pi_{d=1}^M P(\boldsymbol{w_d}|\boldsymbol{y_d}, \boldsymbol{\theta})$ in training documents $D = \{(\boldsymbol{w_d}, \boldsymbol{y_d})\}_{d=1}^M$. Function g corresponding to a document d is introduced as follows:

$$g_{iv}^d(\boldsymbol{\theta}) = \frac{h(\boldsymbol{y_d})\theta_{iv}}{\sum_{j=1}^K h_j(\boldsymbol{y_d})\theta_{jv}} \tag{2}$$

The parameters are updated along with the following formula.

$$\theta_{iv}^{(t+1)} = \frac{1}{C}(\sum_d^M x_{dv} g_{iv}^d(\boldsymbol{\theta}^{(t)}) + \zeta - 1) \tag{3}$$

x_{dv} is the frequency of word v in document d. C is the normalization term for $\sum_{v=1}^V \theta_{iv} = 1$. ζ is a smoothing parameter that is *Laplace smoothing* when ζ is set to two. In this paper, ζ is set to two as the original paper.

4 Proposed Model

In this section, firstly, we mention the problem related to PMM. Then, we explain our solution of the problem by proposing a new model.

4.1 Overview

PMM estimates model parameter $\boldsymbol{\theta}$ assuming that all of mixture ratios of single topic are equal. It is our intuition that each document can sometimes be more weighted to some topics than to the rest of the assigned topics. If the topic weightings are averaged over all biases in the whole document set, they could be canceled. Therefore, model parameter $\boldsymbol{\theta}$ learned by PMM can be reasonable over the whole of documents.

However, if we compute the probability of generating an individual document, a document-specific topic weight bias on mixture ratio is to be considered. The proposed model takes into account this document-specific bias by assuming that mixture ratio vector $\boldsymbol{\pi}$ follows Dirichlet distribution. This is because we assume the sum of the element in vector $\boldsymbol{\pi}$ is one and each element π_i is nonnegative. Namely, the proposed model assumes model parameter of multiple topics as a mixture of model parameter on each single topic with mixture ratio following Dirichlet distribution. Concretely, given a document $\boldsymbol{w}$ and multiple topics $\boldsymbol{y}$, it estimates a posterior probability distribution $P(\boldsymbol{\pi}|\boldsymbol{x}, \boldsymbol{y})$ by Bayesian inference. For convenience, the proposed model is called PDMM(Parametric Dirichlet Mixture Model).

In Figure 1, the mixture ratio(bias) $\boldsymbol{\pi} = (\pi_1, \pi_2, \pi_3), \sum_{i=1}^{3} \pi_i = 1, \pi_i > 0$ of three topics is expressed in 3-dimensional real space $\boldsymbol{R}^3$. The mixture ratio(bias) $\boldsymbol{\pi}$ constructs 2D-simplex in $\boldsymbol{R}^3$. One point on the simplex indicates one mixture ratio $\boldsymbol{\pi}$ of the three topics. That is, the point indicates multiple topics with the mixture ratio. PMM generates documents assuming that each mixture ratio is equal. That is, PMM generates only documents with multiple topics that indicates the center point of the 2D-simplex in Figure 1. On the contrary, PDMM generates documents assuming that mixture ratio $\boldsymbol{\pi}$ follows Dirichlet distribution. That is, PDMM can generate documents with multiple topics whose weights can be generated by Dirichlet distribution.

4.2 Formulation

PDMM is formulated as follows:

$$P(\boldsymbol{w}|\boldsymbol{y}, \boldsymbol{\alpha}, \boldsymbol{\theta})$$

$$= \int P(\boldsymbol{\pi}|\boldsymbol{\alpha}, \boldsymbol{y}) \Pi_{v=1}^{V} (\varphi(v, \boldsymbol{y}, \boldsymbol{\theta}, \boldsymbol{\pi}))^{x_v} d\boldsymbol{\pi} \qquad (4)$$

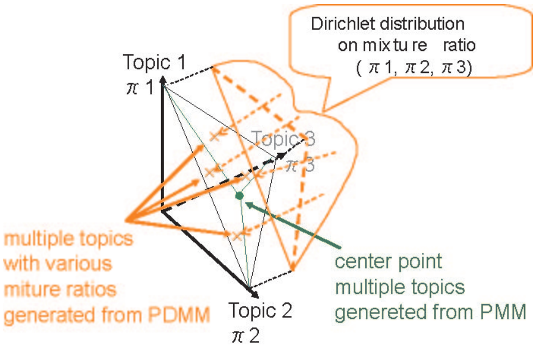

Figure 1: Topic Simplex for Three Topics

$\boldsymbol{\pi}$ is a vector whose element is $\pi_i (i \in I_y)$. π_i is a mixture ratio(bias) of model parameter corresponding to single topic i where $\pi_i > 0, \sum_{i \in I_y} \pi_i = 1$. π_i can be considered as a probability of topic i , i.e., $\pi_i = P(y_i = 1|\boldsymbol{\pi})$. $P(\boldsymbol{\pi}|\boldsymbol{\alpha}, \boldsymbol{y})$ is a prior distribution of $\boldsymbol{\pi}$ whose index i is an element of I_y, i.e., $i \in I_y$. We use Dirichlet distribution as the prior. $\boldsymbol{\alpha}$ is a parameter vector of Dirichlet distribution corresponding to $\pi_i (i \in I_y)$. Namely, the formulation is as follows.

$$P(\boldsymbol{\pi}|\boldsymbol{\alpha}, \boldsymbol{y}) = \frac{\Gamma(\sum_{i \in I_y} \alpha_i)}{\Pi_{i \in I_y} \Gamma(\alpha_i)} \Pi_{i \in I_y} \pi_i^{\alpha_i - 1} \qquad (5)$$

$\varphi(v, \boldsymbol{y}, \boldsymbol{\theta}, \boldsymbol{\pi})$ is the probability that word v is generated from multiple topics $\boldsymbol{y}$ and is denoted as a linear sum of $\pi_i (i \in I_y)$ and $\theta_{iv} (i \in I_y)$ as follows.

$$\varphi(v, \boldsymbol{y}, \boldsymbol{\theta}, \boldsymbol{\pi}) = \sum_{i \in I_y} \pi_i \theta_{iv} \qquad (6)$$

$$= \sum_{i \in I_y} P(y_i = 1|\boldsymbol{\pi}) P(v|y_i = 1, \theta) \qquad (7)$$

4.3 Variational Bayes Method for Estimating Mixture Ratio

This section explains a method to estimate the posterior probability distribution $P(\boldsymbol{\pi}|\boldsymbol{w}, \boldsymbol{y}, \boldsymbol{\alpha}, \boldsymbol{\theta})$ of a document-specific mixture ratio. Basically, $P(\boldsymbol{\pi}|\boldsymbol{w}, \boldsymbol{y}, \boldsymbol{\alpha}, \boldsymbol{\theta})$ is obtained by Bayes theorem using Eq.(4). However, that is computationally impractical because a complicated integral computation is needed. Therefore we estimate an approximate distribution of $P(\boldsymbol{\pi}|\boldsymbol{w}, \boldsymbol{y}, \boldsymbol{\alpha}, \boldsymbol{\theta})$ using Variational Bayes Method(H.Attias, 1999). The concrete explanation is as follows

Use Eqs.(4)(7).

$$P(\boldsymbol{w}, \boldsymbol{\pi}|\boldsymbol{y}, \boldsymbol{\alpha}, \boldsymbol{\theta}) =$$
$$P(\boldsymbol{\pi}|\boldsymbol{\alpha}, \boldsymbol{y})\Pi_{v=1}^{V}(\sum_{i\in I_y} P(y_i = 1|\boldsymbol{\pi})P(v|y_i = 1, \theta))^{x_v}$$

Transform document expression of above equation into words vector $\boldsymbol{w} = (w_1, w_2, \cdots, w_N)$.

$$P(\boldsymbol{w}, \boldsymbol{\pi}|\boldsymbol{y}, \boldsymbol{\alpha}, \boldsymbol{\theta}) =$$
$$P(\boldsymbol{\pi}|\boldsymbol{\alpha}, \boldsymbol{y})\Pi_{n=1}^{N} \sum_{i_n\in I_y} P(y_{i_n} = 1|\boldsymbol{\pi})P(w_n|y_{i_n} = 1, \theta)$$

By changing the order of $\sum$ and Π, we have

$$P(\boldsymbol{w}, \boldsymbol{\pi}|\boldsymbol{y}, \boldsymbol{\alpha}, \boldsymbol{\theta}) =$$
$$P(\boldsymbol{\pi}|\boldsymbol{\alpha}, \boldsymbol{y}) \sum_{\boldsymbol{i}\in I_y^N} \Pi_{n=1}^{N} P(y_{i_n} = 1|\boldsymbol{\pi})P(w_n|y_{i_n} = 1, \theta)$$
$$(\sum_{\boldsymbol{i}\in I_y^N} \equiv \sum_{i_1\in I_y}\sum_{i_2\in I_y}\cdots\sum_{i_N\in I_y})$$

Express $y_{i_n} = 1$ as $z_n = i$.

$$P(\boldsymbol{w}|\boldsymbol{y}, \boldsymbol{\alpha}, \boldsymbol{\theta}) =$$
$$\int \sum_{\boldsymbol{z}\in I_y^N} P(\boldsymbol{\pi}|\boldsymbol{\alpha}, \boldsymbol{y})\Pi_{n=1}^{N} P(z_n|\boldsymbol{\pi})P(w_n|z_n, \theta)d\boldsymbol{\pi}$$
$$(\sum_{\boldsymbol{z}\in I_y^N} \equiv \sum_{z_1\in I_y}\sum_{z_2\in I_y}\cdots\sum_{z_N\in I_y}) \qquad (8)$$

Eq.(8) is regarded as Eq.(4) rewritten by introducing a new latent variable $\boldsymbol{z} = (z_1, z_2, \cdots, z_N)$.

$$P(\boldsymbol{w}|\boldsymbol{y}, \boldsymbol{\alpha}, \boldsymbol{\theta}) = \int \sum_{\boldsymbol{z}\in I_y^N} P(\boldsymbol{\pi}, \boldsymbol{z}, \boldsymbol{w}|\boldsymbol{y}, \boldsymbol{\alpha}, \boldsymbol{\theta})d\boldsymbol{\pi} \quad (9)$$

Use Eqs.(8)(9)

$$P(\boldsymbol{\pi}, \boldsymbol{z}, \boldsymbol{w}|\boldsymbol{y}, \boldsymbol{\alpha}, \boldsymbol{\theta})$$
$$= P(\boldsymbol{\pi}|\boldsymbol{\alpha}, \boldsymbol{y})\Pi_{n=1}^{N} P(z_n|\boldsymbol{\pi})P(w_n|z_n, \theta) \qquad (10)$$

Hereafter, we explain Variational Bayes Method for estimating an approximate distribution of $P(\boldsymbol{\pi}, \boldsymbol{z}|\boldsymbol{w}, \boldsymbol{y}, \boldsymbol{\alpha}, \boldsymbol{\theta})$ using Eq.(10). This approach is the same as LDA(D.M.Blei et al., 2001; D.M.Blei et al., 2003). The approximate distribution is assumed to be $Q(\boldsymbol{\pi}, \boldsymbol{z}|\gamma, \boldsymbol{\phi})$. The following assumptions are introduced.

$$Q(\boldsymbol{\pi}, \boldsymbol{z}|\gamma, \boldsymbol{\phi}) = Q(\boldsymbol{\pi}|\gamma)Q(\boldsymbol{z}|\boldsymbol{\phi}) \qquad (11)$$
$$Q(\boldsymbol{\pi}|\gamma) = \frac{\Gamma(\sum_{i\in I_y}\gamma_i)}{\Pi_{i\in I_y}\Gamma(\gamma_i)}\Pi_{i\in I_y}\pi_i^{\gamma_i - 1} \qquad (12)$$
$$Q(\boldsymbol{z}|\boldsymbol{\phi}) = \Pi_{n=1}^{N} Q(z_n|\boldsymbol{\phi}) \qquad (13)$$
$$Q(z_n|\boldsymbol{\phi}) = \Pi_{i=1}^{K}(\phi_{ni})^{z_n^i} \qquad (14)$$

$Q(\boldsymbol{\pi}|\gamma)$ is Dirichlet distribution where γ is its parameter. $Q(z_n|\boldsymbol{\phi})$ is Multinomial distribution where ϕ_{ni} is its parameter and indicates the probability that the nth word of a document is topic i, i.e. $P(y_{i_n} = 1)$. z_n^i is a value of 1(0) when z_n is (not) i. According to Eq.(11), $Q(\boldsymbol{\pi}|\gamma)$ is regarded as an approximate distribution of $P(\boldsymbol{\pi}|\boldsymbol{w}, \boldsymbol{y}, \boldsymbol{\alpha}, \boldsymbol{\theta})$

The log likelihood of $P(\boldsymbol{w}|\boldsymbol{y}, \boldsymbol{\alpha}, \boldsymbol{\theta})$ is derived as follows.

$$\log P(\boldsymbol{w}|\boldsymbol{y}, \boldsymbol{\alpha}, \boldsymbol{\theta})$$
$$= \int \sum_{\boldsymbol{z}\in I_y^N} Q(\boldsymbol{\pi}, \boldsymbol{z}|\gamma, \boldsymbol{\phi})d\boldsymbol{\pi} \log P(\boldsymbol{w}|\boldsymbol{y}, \boldsymbol{\alpha}, \boldsymbol{\theta})$$
$$= \int \sum_{\boldsymbol{z}\in I_y^N} Q(\boldsymbol{\pi}, \boldsymbol{z}|\gamma, \boldsymbol{\phi}) \log \frac{P(\boldsymbol{\pi}, \boldsymbol{z}, \boldsymbol{w}|\boldsymbol{y}, \boldsymbol{\alpha}, \boldsymbol{\theta})}{Q(\boldsymbol{\pi}, \boldsymbol{z}|\gamma, \boldsymbol{\phi})}d\boldsymbol{\pi}$$
$$+ \int \sum_{\boldsymbol{z}\in I_y^N} Q(\boldsymbol{\pi}, \boldsymbol{z}|\gamma, \boldsymbol{\phi}) \log \frac{Q(\boldsymbol{\pi}, \boldsymbol{z}|\gamma, \boldsymbol{\phi})}{P(\boldsymbol{\pi}, \boldsymbol{z}|\boldsymbol{w}, \boldsymbol{y}, \boldsymbol{\alpha}, \boldsymbol{\theta})}d\boldsymbol{\pi}$$

$$\log P(\boldsymbol{w}|\boldsymbol{y}, \boldsymbol{\alpha}, \boldsymbol{\theta}) = \mathscr{F}[Q] + KL(Q, P) \qquad (15)$$

$$\mathscr{F}[Q] = \int \textstyle\sum_{\boldsymbol{z}\in I_y^N} Q(\boldsymbol{\pi}, \boldsymbol{z}|\gamma, \boldsymbol{\phi}) \log \frac{P(\boldsymbol{\pi}, \boldsymbol{z}, \boldsymbol{w}|\boldsymbol{y}, \boldsymbol{\alpha}, \boldsymbol{\theta})}{Q(\boldsymbol{\pi}, \boldsymbol{z}|\gamma, \boldsymbol{\phi})}d\boldsymbol{\pi}$$
$$KL(Q, P) = \int \textstyle\sum_{\boldsymbol{z}\in I_y^N} Q(\boldsymbol{\pi}, \boldsymbol{z}|\gamma, \boldsymbol{\phi}) \log \frac{Q(\boldsymbol{\pi}, \boldsymbol{z}|\gamma, \boldsymbol{\phi})}{P(\boldsymbol{\pi}, \boldsymbol{z}|\boldsymbol{w}, \boldsymbol{y}, \boldsymbol{\alpha}, \boldsymbol{\theta})}d\boldsymbol{\pi}$$

$KL(Q, P)$ is the Kullback-Leibler Divergence that is often employed as a distance between probability distributions. Namely, $KL(Q, P)$ indicates a distance between $Q(\boldsymbol{\pi}, \boldsymbol{z}|\gamma, \boldsymbol{\phi})$ and $P(\boldsymbol{\pi}, \boldsymbol{z}|\boldsymbol{w}, \boldsymbol{y}, \boldsymbol{\alpha}, \boldsymbol{\theta})$. $\log P(\boldsymbol{w}|\boldsymbol{y}, \boldsymbol{\alpha}, \boldsymbol{\theta})$ is not relevant to $Q(\boldsymbol{\pi}, \boldsymbol{z}|\gamma, \boldsymbol{\phi})$. Therefore, $Q(\boldsymbol{\pi}, \boldsymbol{z}|\gamma, \boldsymbol{\phi})$ that maximizes $\mathscr{F}[Q]$ minimizes $KL(Q, P)$, and gives a good approximate distribution of $P(\boldsymbol{\pi}, \boldsymbol{z}|\boldsymbol{w}, \boldsymbol{y}, \boldsymbol{\alpha}, \boldsymbol{\theta})$.

We estimate $Q(\boldsymbol{\pi}, \boldsymbol{z}|\gamma, \boldsymbol{\phi})$, concretely its parameter $\boldsymbol{\gamma}$ and $\boldsymbol{\phi}$, by maximizing $\mathscr{F}[Q]$ as follows.

Using Eqs.(10)(11).

$$\mathscr{F}[Q] = \int Q(\boldsymbol{\pi}|\gamma) \log P(\boldsymbol{\pi}|\boldsymbol{\alpha}, \boldsymbol{y})d\boldsymbol{\theta} \qquad (16)$$
$$+ \int \sum_{\boldsymbol{z}\in I_y^N} Q(\boldsymbol{\pi}|\gamma)Q(\boldsymbol{z}|\boldsymbol{\phi}) \log \Pi_{n=1}^{N} P(z_n|\boldsymbol{\pi})d\boldsymbol{\theta} \quad (17)$$
$$+ \sum_{\boldsymbol{z}\in I_y^N} Q(\boldsymbol{z}|\boldsymbol{\phi}) \log \Pi_{n=1}^{N} P(w_n|z_n, \theta) \qquad (18)$$
$$- \int Q(\boldsymbol{\pi}|\gamma) \log Q(\boldsymbol{\pi}|\gamma)d\boldsymbol{\theta} \qquad (19)$$
$$- \sum_{\boldsymbol{z}\in I_y^N} Q(\boldsymbol{z}|\boldsymbol{\phi}) \log Q(\boldsymbol{z}|\boldsymbol{\phi}) \qquad (20)$$

$$\begin{aligned} = \quad & \log\Gamma(\textstyle\sum_{i\in I_y}\alpha_j) - \sum_{i\in I_y}\log\Gamma(\alpha_i) \\ & + \textstyle\sum_{i\in I_y}(\alpha_i - 1)(\Psi(\gamma_i) - \Psi(\sum_{j\in I_y}\gamma_j)) \end{aligned} \tag{21}$$

$$+ \quad \sum_{n=1}^{N}\sum_{i\in I_y}\phi_{ni}(\Psi(\gamma_i) - \Psi(\sum_{j\in I_y}\gamma_j)) \tag{22}$$

$$+ \quad \sum_{n=1}^{N}\sum_{i\in I_y}\sum_{j=1}^{V}\phi_{ni}w_n^j \log\theta ij \tag{23}$$

$$\begin{aligned} - \quad & \log\Gamma(\sum_{j\in I_y}\gamma_j) + \sum_{i\in I_y}\log\Gamma(\sum_{j\in I_y}\gamma_j) \\ & -\sum_{i\in I_y}(\gamma_i - 1)(\Psi(\gamma_i) - \Psi(\sum_{j\in I_y}\gamma_j)) \end{aligned} \tag{24}$$

$$- \quad \sum_{n=1}^{N}\sum_{i\in I_y}\phi_{ni}\log\phi_{ni} \tag{25}$$

$\mathscr{F}[Q]$ is known to be a function of γ_i and ϕ_{ni} from Eqs.(21) through (25). Then we only need to resolve the maximization problem of nonlinear function $\mathscr{F}[Q]$ with respect to γ_i and ϕ_{ni}. In this case, the maximization problem can be resolved by Lagrange multiplier method.

First, regard $\mathscr{F}[Q]$ as a function of γ_i, which is denoted as $\mathscr{F}[\gamma_i]$. Then ,γ_i does not have constraints. Therefore we only need to find the following γ_i, where $\frac{\partial\mathscr{F}[\gamma_i]}{\partial\gamma_i} = 0$. The resultant γ_i is expressed as follows.

$$\gamma_i = \alpha_i + \sum_{n=1}^{N}\phi_{ni} \quad (i \in I_y) \tag{26}$$

Second, regard $\mathscr{F}[Q]$ as a function of ϕ_{ni}, which is denoted as $\mathscr{F}[\phi_{ni}]$. Then, considering the constraint that $\sum_{i\in I_y}\phi_{ni} = 1$, Lagrange function $L[\phi_{ni}]$ is expressed as follows:

$$L[\phi_{ni}] = \mathscr{F}[\phi_{ni}] + \lambda(\sum_{i\in I_y}\phi_{ni} - 1) \tag{27}$$

λ is a so-called Lagrange multiplier.

We find the following ϕ_{ni} where $\frac{\partial L[\phi_{ni}]}{\partial\phi ni} = 0$.

$$\phi_{ni} = \frac{\theta_{iw_n}}{C}\exp(\Psi(\gamma_i) - \Psi(\sum_{j\in I_y}\gamma_j)) \ \ (i \in I_y)) \tag{28}$$

C is a normalization term. By Eqs.(26)(28), we obtain the following updating formulas of γ_i and ϕ_{ni}.

$$\gamma_i^{(t+1)} = \alpha_i + \sum_{n=1}^{N}\phi_{ni}^{(t)} \quad (i \in I_y) \tag{29}$$

$$\phi_{ni}^{(t+1)} = \frac{\theta_{iw_n}}{C}\exp(\Psi(\gamma_i^{(t+1)}) - \Psi(\sum_{j\in I_y}\gamma_j^{(t+1)})) \tag{30}$$

Using the above updating formulas , we can estimate parameters $\boldsymbol{\gamma}$ and $\boldsymbol{\phi}$, which are specific to a document $\boldsymbol{w}$ and topics $\boldsymbol{y}$. Last of all , we show a pseudo code :$vb(\boldsymbol{w},\boldsymbol{y})$ which estimates γ and ϕ. In addition , we regard $\boldsymbol{\alpha}$, which is a parameter of a prior distribution of $\boldsymbol{\pi}$, as a vector whose elements are all one. That is because Dirichlet distribution where each parameter is one becomes Uniform distribution.

• Variational Bayes Method for PDMM————function vb($\boldsymbol{w},\boldsymbol{y}$):

```
1. Initialize $\alpha_i \leftarrow 1 \ \forall i \in I_y$
2. Compute $\boldsymbol{\gamma^{(t+1)}},\boldsymbol{\phi^{(t+1)}}$ using Eq.(29)(30)
3. if $\parallel \boldsymbol{\gamma^{(t+1)}} - \boldsymbol{\gamma^{(t)}} \parallel < \epsilon$
   & $\parallel \boldsymbol{\phi^{(t+1)}} - \boldsymbol{\phi^{(t)}} \parallel < \epsilon$
4. then return $(\boldsymbol{\gamma^{(t+1)}},\boldsymbol{\phi^{(t+1)}})$ and halt
5. else $t \leftarrow t+1$ and goto step (2)
```

4.4 Computing Probability of Generating Document

PMM computes a probability of generating a document $\boldsymbol{w}$ on topics $\boldsymbol{y}$ and a set of model parameter Θ as follows:

$$P(\boldsymbol{w}|\boldsymbol{y},\Theta) = \Pi_{v=1}^{V}(\varphi(v,\boldsymbol{y},\boldsymbol{\theta}))^{x_v} \tag{31}$$

$\varphi(v,\boldsymbol{y},\boldsymbol{\theta})$ is the probability of generating a word v on topics $\boldsymbol{y}$ that is a mixture of model parameter $\theta_{iv}(i \in I_y)$ with an equal mixture ratio. On the other hand, PDMM computes the probability of generating a word v on topics $\boldsymbol{y}$ using $\theta_{iv}(i \in I_y)$ and an approximate posterior distribution $Q(\pi|\boldsymbol{\gamma})$ as follows:

$$\begin{aligned}\varphi(v, \boldsymbol{y}, \boldsymbol{\theta}, \boldsymbol{\gamma}) & \\ &= \int (\sum_{i \in I_y} \pi_i \theta_{iv}) Q(\boldsymbol{\pi}|\boldsymbol{\gamma}) d\boldsymbol{\pi} & (32) \\ &= \sum_{i \in I_y} \int \pi_i Q(\pi|\boldsymbol{\gamma}) d\boldsymbol{\pi} \theta_{iv} & (33) \\ &= \sum_{i \in I_y} \tilde{\pi}_i \theta_{iv} & (34)\end{aligned}$$

$\tilde{\pi}_i = \int \pi_i Q(\pi|\boldsymbol{\gamma}) d\boldsymbol{\pi} = \frac{\gamma_i}{\sum_{j \in I_y} \gamma_j}$ (C.M.Bishop, 2006)

The above equation regards the mixture ratio of topics $\boldsymbol{y}$ of a document $\boldsymbol{w}$ as the expectation $\tilde{\pi}_i (i \in I_y)$ of $Q(\pi|\boldsymbol{\gamma})$. Therefore, a probability of generating $\boldsymbol{w}$ $P(\boldsymbol{w}|\boldsymbol{y}, \Theta)$ is computed with $\varphi(v, \boldsymbol{y}, \boldsymbol{\theta}, \boldsymbol{\gamma})$ estimated in the following manner:

$$P(\boldsymbol{w}|\boldsymbol{y}, \Theta) = \Pi_{v=1}^{V} (\varphi(v, \boldsymbol{y}, \boldsymbol{\theta}, \boldsymbol{\gamma})))^{x_v} \qquad (35)$$

4.5 Algorithm for Estimating Multiple Topics of Document

PDMM estimates multiple topics $\boldsymbol{y}^*$ maximizing a probability of generating a document $\boldsymbol{w}^*$, i.e., Eq.(35). This is the 0-1 integer problem(i.e., NP-hard problem), so PDMM uses the same approximate estimation algorithm as PMM does. But it is different from PMM's estimation algorithm in that it estimates the mixture ratios of topics $\boldsymbol{y}$ by Variational Bayes Method as shown by vb(w,y) at step 6 in the following pseudo code of the estimation algorithm:

```
• Topics Estimation Algorithm
function prediction($\boldsymbol{w}$):
1. Initialize $S \leftarrow \{1, 2, \cdots\}, y_i \leftarrow 0$ for $i(1, 2 \cdots, K)$
2. $v_{max} \leftarrow -\infty$
3. while $S$ is not empty do
4.     foreach $i \in S$ do
5.         $y_i \leftarrow 1, y_{j \in S \setminus i} \leftarrow 0$
6.         Compute $\boldsymbol{\gamma}$ by vb($\boldsymbol{w}, \boldsymbol{y}$)
7.         $v(i) \leftarrow P(\boldsymbol{w}|\boldsymbol{y})$
8.     end foreach
9.     $i^* \leftarrow$ argmax $v(i)$
10.    if $v(i^*) > v_{max}$
11.        $y_{i^*} \leftarrow 1, S \leftarrow S \setminus i^*, v_{max} \leftarrow v(i^*)$
12.    else
13.        return $\boldsymbol{y}$ and halt
```

5 Evaluation

We evaluate the proposed model by using F-measure of multiple topics categorization problem.

5.1 Dataset

We use MEDLINE[1] as a dataset. In this experiment, we use five thousand abstracts written in English. MEDLINE has a metadata set called MeSH Term. For example, each abstract has MeSH Terms such as RNA Messenger and DNA-Binding Proteins. MeSH Terms are regarded as multiple topics of an abstract. In this regard, however, we use MeSH Terms whose frequency are medium(100-999). We did that because the result of experiment can be overly affected by such high frequency terms that appear in almost every abstract and such low frequency terms that appear in very few abstracts. In consequence, the number of topics is 88. The size of vocabulary is 46,075. The proportion of documents with multiple topics on the whole dataset is 69.8%, i.e., that of documents with single topic is 30.2%. The average of the number of topics of a document is 3.4. Using TreeTagger[2], we lemmatize every word. We eliminate stop words such as articles and be-verbs.

5.2 Result of Experiment

We compare F-measure of PDMM with that of PMM and other models.

F-measure(F) is as follows:
$F = \frac{2PR}{P+R}, P = \frac{|N_r \cap N_e|}{|N_e|}, R = \frac{|N_r \cap N_e|}{|N_r|}$.

N_r is a set of relevant topics . N_e is a set of estimated topics. A higher F-measure indicates a better ability to discriminate topics. In our experiment, we compute F-measure in each document and average the F-measures throughout the whole document set.

We consider some models that are distinct in learning model parameter $\boldsymbol{\theta}$. **PDMM** learns model parameter $\boldsymbol{\theta}$ by the same learning algorithm as PMM. **NBM** learns model parameter $\boldsymbol{\theta}$ by Naive Bayes learning algorithm. The parameters are updated according to the following formula: $\theta_{iv} = \frac{M_{iv}+1}{C}$. M_{iv} is the number of training documents where a word v appears in topic i. C is normalization term for $\sum_{v=1}^{V} \theta_{iv} = 1$.

[1] http://www.nlm.nih.gov/pubs/factsheets/medline.html

[2] http://www.ims.uni-stuttgart.de/projekte/corplex/TreeTagger/

The comparison of these models with respect to F-measure is shown in Figure 2. The horizontal axis is the proportion of test data of dataset(5,000 abstracts). For example, 2% indicates that the number of documents for learning model is 4,900 and the number of documents for the test is 100. The vertical axis is F-measure. In each proportion, F-measure is an average value computed from five pairs of training documents and test documents randomly generated from dataset.

F-measure of PDMM is higher than that of other methods on any proportion, as shown in Figure 2. Therefore, PDMM is more effective than other methods on multiple topics categorization.

Figure 3 shows the comparison of models with respect to F-measure, changing proportion of multiple topic document for the whole dataset. The proportion of document for learning and test are 40% and 60%, respectively. The horizontal axis is the proportion of multiple topic document on the whole dataset. For example, 30% indicates that the proportion of multiple topic document is 30% on the whole dataset and the remaining documents are single topic , that is, this dataset is almost single topic document. In 30%. there is little difference of F-measure among models. As the proportion of multiple topic and single topic document approaches 90%, that is, multiple topic document, the differences of F-measure among models become apparent. This result shows that PDMM is effective in modeling multiple topic document.

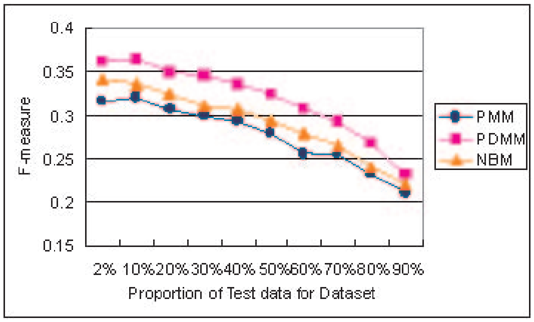

Figure 2: F-measure Results

5.3 Discussion

In the results of experiment described in section 5.2, PDMM is more effective than other models in multiple-topic categorization. If the topic weightings are averaged over all biases in the whole of training documents, they could be canceled. This cancellation can lead to the result that model parameter $\boldsymbol{\theta}$ learned by PMM is reasonable over the whole of documents. Moreover, PDMM computes the probability of generating a document using a mixture of model parameter, estimating the mixture ratio of topics. This estimation of the mixture ratios, we think, is the key factor to achieve the results better than other models. In addition, the estimation of a mixture ratio of topics can be effective from the perspective of extracting features of a document with multiple topics. A mixture ratio of topics assigned to a document is specific to the document. Therefore, the estimation of the mixture ratio of topics is regarded as a projection from a word-frequency space of $\mathscr{Q}^V$ where $\mathscr{Q}$ is a set of integer number to a mixture ratio space of topics $[0, 1]^K$ in a document. Since the size of vocabulary is much more than that of topics, the estimation of the mixture ratio of topics is regarded as a dimension reduction and an extraction of features in a document. This can lead to analysis of similarity among documents with multiple topics. For example, the estimated mixture ratio of topics [Comparative Study]C[Apoptosis] and [Models,Biological] in one MEDLINE abstract is 0.656C0.176 and 0.168, respectively. This ratio can be a feature of this document.

Moreover, we can obtain another interesting results as follows. The estimation of mixture ratios of topics uses parameter γ in section 4.3. We obtain interesting results from another parameter ϕ that needs to estimate γ. ϕ_{ni} is specific to a document. A

ϕ_{ni} indicates the probability that a word w_n belongs to topic i in a document. Therefore we can compute the entropy on w_n as follows:

$$entropy(w_n) = \sum_{i=1}^{K} \phi_{ni} \log(\phi_{ni})$$

We rank words in a document by this entropy. For example, a list of words in ascending order of the entropy in document X is shown in Table 1. A value in parentheses is a ranking of words in decending order of TF-IDF($= tf \cdot \log(M/df)$,where tf is term frequency in a test document, df is document frequency and M is the number of documents in the set of doucuments for learning model parameters) (Y. Yang and J. Pederson, 1997) . The actually assigned topics are [Female] , [Male] and [Biological Markers], where each estimated mixture ratio is 0.499 , 0.460 and 0.041, respectively.

The top 10 words seem to be more technical than the bottom 10 words in Table 1. When the entropy of a word is lower, the word is more topic-specific oriented, i.e., more technical . In addition, this ranking of words depends on topics assigned to a document. When we assign randomly chosen topics to the same document, generic terms might be ranked higher. For example, when we rondomly assign the topics [Rats], [Child] and [Incidence], generic terms such as ”use” and ”relate” are ranked higher as shown in Table 2. The estimated mixture ratio of [Rats], [Child] and [Incidence] is 0.411, 0.352 and 0.237, respectively.

For another example, a list of words in ascending order of the entropy in document Y is shown in Table 3. The actually assigned topics are Female, Animals, Pregnancy and Glucose.. The estimated mixture ratio of [Female], [Animals] ,[Pregnancy] and [Glucose] is 0.442, 0.437, 0.066 and 0.055, respectively In this case, we consider assigning sub topics of actual topics to the same document Y.

Table 4 shows a list of words in document Y assigned with the sub topics [Female] and [Animals]. The estimated mixture ratio of [Female] and [Animals] is 0.495 and 0.505, respectively. Estimated mixture ratio of topics is chaged. It is interesting that [Female] has higher mixture ratio than [Animals] in actual topics but [Female] has lower mixture ratio than [Animals] in sub topics [Female] and [Animals]. According to these different mixture ratios, the ranking of words in docment Y is changed.

Table 5 shows a list of words in document Y assigned with the sub topics [Pregnancy] and [Glucose]. The estimated mixture ratio of [Pregnancy] and [Glucose] is 0.502 and 0.498, respectively. It is interesting that in actual topics, the ranking of gglucose-insulinh and ”IVGTT” is high in document Y but in the two subset of actual topics, gglucose-insulinh and ”IVGTT” cannot be find in Top 10 words.

The important observation known from these examples is that this ranking method of words in a document can be assosiated with topics assigned to the document. ϕ depends on γ seeing Eq.(28). This is because the ranking of words depends on assigned topics, concretely, mixture ratios of assigned topics. TF-IDF computed from the whole documents cannot have this property. Combined with existing the extraction method of keywords, our model has the potential to extract document-specific keywords using information of assigned topics.

Table 3: Word List of Document Y whose Actual Topics are [Femaile],[Animals],[Pregnancy] and [Glucose]

6 Concluding Remarks

We proposed and evaluated a novel probabilistic generative models, PDMM, to deal with multiple-topic documents. We evaluated PDMM and other models by comparing F-measure using MEDLINE corpus. The results showed that PDMM is more effective than PMM. Moreover, we indicate the potential of the proposed model that extracts document-specific keywords using information of assigned topics.

Abstract

We address the problem of smoothing translation probabilities in a bilingual N-gram-based statistical machine translation system. It is proposed to project the bilingual tuples onto a continuous space and to estimate the translation probabilities in this representation. A neural network is used to perform the projection and the probability estimation.

Smoothing probabilities is most important for tasks with a limited amount of training material. We consider here the BTEC task of the 2006 IWSLT evaluation. Improvements in all official automatic measures are reported when translating from Italian to English. Using a continuous space model for the translation model and the target language model, an improvement of 1.5 BLEU on the test data is observed.

1 Introduction

The goal of statistical machine translation (SMT) is to produce a target sentence $\mathbf{e}$ from a source sentence $\mathbf{f}$. Among all possible target language sentences the one with the highest probability is chosen:

$$\mathbf{e}^* = \arg\max_{\mathbf{e}} \Pr(\mathbf{e}|\mathbf{f}) = \arg\max_{\mathbf{e}} \Pr(\mathbf{f}|\mathbf{e}) \Pr(\mathbf{e})$$

where $\Pr(\mathbf{f}|\mathbf{e})$ is the translation model and $\Pr(\mathbf{e})$ is the target language model. This approach is usually referred to as the *noisy source-channel* approach in statistical machine translation (Brown et al., 1993).

During the last few years, the use of context in SMT systems has provided great improvements in translation. SMT has evolved from the original word-based approach to phrase-based translation systems (Och et al., 1999; Koehn et al., 2003). A phrase is defined as a group of source words $\tilde{\mathbf{f}}$ that should be translated together into a group of target words $\tilde{\mathbf{e}}$. The translation model in phrase-based systems includes the phrase translation probabilities in both directions, i.e. $P(\tilde{\mathbf{e}}|\tilde{\mathbf{f}})$ and $P(\tilde{\mathbf{f}}|\tilde{\mathbf{e}})$.

The use of a maximum entropy approach simplifies the introduction of several additional models explaining the translation process :

$$\begin{aligned} \mathbf{e}^* &= \arg\max p(\mathbf{e}|\mathbf{f}) \\ &= \arg\max_{e} \{exp(\sum_i \lambda_i h_i(\mathbf{e}, \mathbf{f}))\} \end{aligned} \quad (1)$$

The feature functions h_i are the system models and the λ_i weights are typically optimized to maximize a scoring function on a development set (Och and Ney, 2002).

The phrase translation probabilities $P(\tilde{\mathbf{e}}|\tilde{\mathbf{f}})$ and $P(\tilde{\mathbf{f}}|\tilde{\mathbf{e}})$ are usually obtained using relative frequency estimates. Statistical learning theory, however, tells us that relative frequency estimates have several drawbacks, in particular high variance and low bias. Phrase tables may contain several millions of entries, most of which appear only once or twice, which means that we are confronted with a data sparseness problem. Surprisingly, there seems to be little work addressing the issue of smoothing of the phrase table probabilities.

On the other hand, smoothing of relative frequency estimates was extensively investigated in the

Proceedings of the 2007 Joint Conference on Empirical Methods in Natural Language Processing and Computational Natural Language Learning, pp. 430–438, Prague, June 2007.

area of language modeling. A systematic comparison can be for instance found in (Chen and Goodman, 1999). Language models and phrase tables have in common that the probabilities of rare events may be overestimated. However, in language modeling probability mass must be redistributed in order to account for the unseen n-grams. Generalization to unseen events is less important in phrase-based SMT systems since the system searches only for the best segmentation and the best matching phrase pair among the existing ones.

We are only aware of one work that performs a systematic comparison of smoothing techniques in phrase-based machine translation systems (Foster et al., 2006). Two types of phrase-table smoothing were compared: black-box and glass-box methods. Black-methods do not look inside phrases but instead treat them as atomic objects. By these means, all the methods developed for language modeling can be used. Glass-box methods decompose $P(\tilde{\mathbf{e}}|\tilde{\mathbf{f}})$ into a set of lexical distributions $P(e|\tilde{\mathbf{f}})$. For instance, it was suggested to use IBM-1 probabilities (Och et al., 2004), or other lexical translation probabilities (Koehn et al., 2003; Zens and Ney, 2004). Some form of glass-box smoothing is now used in all state-of-the-art statistical machine translation systems.

Another approach related to phrase table smoothing is the so-called N-gram translation model (Mariño et al., 2006). In this model, bilingual tuples are used instead of the phrase pairs and n-gram probabilities are considered rather than relative frequencies. Therefore, smoothing is obtained using the standard techniques developed for language modeling. In addition, a context dependence of the phrases is introduced. On the other hand, some restrictions on the segmentation of the source sentence must be used. N-gram-based translation models were extensively compared to phrase-based systems on several tasks and typically achieve comparable performance.

In this paper we propose to investigate improved smoothing techniques in the framework of the N-gram translation model. Despite the undeniable success of n-graam back-off models, these techniques have several drawbacks from a theoretical point of view: the words are represented in a discrete space, the vocabulary. This prevents "true interpolation" of the probabilities of unseen n-grams since a change in this word space can result in an arbitrary change of the n-gram probability. An alternative approach is based on a *continuous representation* of the words (Bengio et al., 2003). The basic idea is to convert the word indices to a continuous representation and to use a probability estimator operating in this space. Since the resulting distributions are smooth functions of the word representation, better generalization to unknown n-grams can be expected. Probability estimation and interpolation in a continuous space is mathematically well understood and numerous powerful algorithms are available that can perform meaningful interpolations even when only a limited amount of training material is available. This approach was successfully applied to language modeling in large vocabulary continuous speech recognition (Schwenk, 2007) and to language modeling in phrase-based SMT systems (Schwenk et al., 2006).

In this paper, we investigate whether this approach is useful to smooth the probabilities involved in the bilingual tuple translation model. Reliable estimation of unseen n-grams is very important in this translation model. Most of the trigram tuples encountered in the development or test data were never seen in the training data. N-gram hit rates are reported in the results section of this paper. We report experimental results for the BTEC corpus as used in the 2006 evaluations of the international workshop on spoken language translation IWSLT (Paul, 2006). This task provides a very limited amount of resources in comparison to other tasks like the translation of journal texts (NIST evaluations) or of parliament speeches (TC-STAR evaluations). Therefore, new techniques must be deployed to take the best advantage of the limited resources. Among the language pairs tested in this years evaluation, Italian to English gave the best BLEU results in this year evaluation. The better the translation quality is, the more it is challenging to outperform it without adding more data. We show that a new smoothing technique for the translation model achieves a significant improvement in the BLEU score for a state-of-the-art statistical translation system.

This paper is organized as follows. In the next section we first describe the baseline statistical machine translation systems. Section 3 presents the architecture and training algorithms of the continuous space translation model and section 4 summarizes the experimental evaluation. The paper concludes with a discussion of future research directions.

2 N-gram-based Translation Model

The N-gram-based translation model has been derived from the finite-state perspective; more specifically, from the work of Casacuberta (2001). However, different from it, where the translation model is implemented by using a finite-state transducer, the N-gram-based system implements a bilingual N-gram model. It actually constitutes a language model of bilingual units, referred to as tuples, which approximates the joint probability between source and target languages by using N-grams, such as described by the following equation:

$$p(\mathbf{e},\mathbf{f}) \approx \prod_{k=1}^{K} p((e,f)_k|(e,f)_{k-1},\ldots,(e,f)_{k-4}) \tag{2}$$

where e refers to target, f to source and $(e,f)_k$ to the k^{th} tuple of a given bilingual sentence pair.

Bilingual units (tuples) are extracted from any word-to-word alignment according to the following constraints:

- a monotonic segmentation of each bilingual sentence pairs is produced,
- no word inside the tuple is aligned to words outside the tuple, and
- no smaller tuples can be extracted without violating the previous constraints.

As a consequence of these constraints, only one segmentation is possible for a given sentence pair.

Two important issues regarding this translation model must be considered. First, it often occurs that a large number of single-word translation probabilities are left out of the model. This happens for all words that are always embedded in tuples containing two or more words, then no translation probability for an independent occurrence of these embedded words will exist. To overcome this problem, the tuple trigram model is enhanced by incorporating 1-gram translation probabilities for all the embedded words detected during the tuple extraction step. These 1-gram translation probabilities are computed from the intersection of both the source-to-target and the target-to-source alignments.

The second issue has to do with the fact that some words linked to NULL end up producing tuples with NULL source sides. Since no NULL is actually expected to occur in translation inputs, this type of tuple is not allowed. Any target word that is linked to NULL is attached either to the word that precedes or the word that follows it. To determine this, an approach based on the IBM1 probabilities was used, as described in (Mariño et al., 2006).

2.1 Additional features

The following feature functions were used in the N-gram-based translation system:

- A **target language model**. In the baseline system, this feature consists of a 4-gram back-off model of words, which is trained from the target side of the bilingual corpus.
- A **source-to-target lexicon model and a target-to-source lexicon model**. These feature, which are based on the lexical parameters of the IBM Model 1, provide a complementary probability for each tuple in the translation table.
- A **word bonus function**. This feature introduces a bonus based on the number of target words contained in the partial-translation hypothesis. It is used to compensate for the system's preference for short output sentences.

All these models are combined in the decoder. Additionally, the decoder allows for a non-monotonic search with the following distorsion model.

- A word distance-based **distorsion model**.

$$P(t_1^K) = exp(-\sum_{k=1}^{K} d_k)$$

where d_k is the distance between the first word of the k^{th} tuple (unit), and the last word+1 of the $(k-1)^{th}$ tuple.

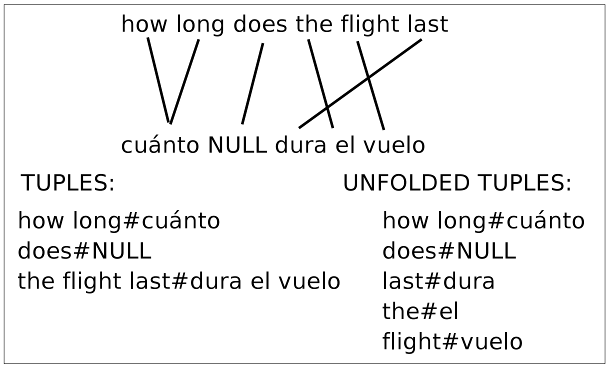

Figure 1: *Comparing regular and unfolded tuples.*

Distance are measured in words referring to the units source side.

To reduce the computational cost we place limits on the search using two parameters: the distortion limit (the maximum distance measured in words that a tuple is allowed to be reordered, m) and the reordering limit (the maximum number of reordering jumps in a sentence, j). Tuples need to be extracted by an unfolding technique (Mariño et al., 2006). This means that the tuples are broken into smaller tuples, and these are sequenced in the order of the target words. In order not to lose the information on the correct order, the decoder performs a non-monotonic search. Figure 1 shows an example of tuple unfolding compared to the monotonic extraction. The unfolding technique produces a different bilingual n-gram language model with reordered source words.

In order to combine the models in the decoder suitably, an optimization tool based on the Simplex algorithm is used to compute log-linear weights for each model.

3 Continuous Space N-gram Models

The architecture of the neural network n-gram model is shown in Figure 2. A standard fully-connected multi-layer perceptron is used. The inputs to the neural network are the indices of the $n-1$ previous units (words or tuples) in the vocabulary $h_j = w_{j-n+1}, \ldots, w_{j-2}, w_{j-1}$ and the outputs are the posterior probabilities of *all* units of the vocabulary:

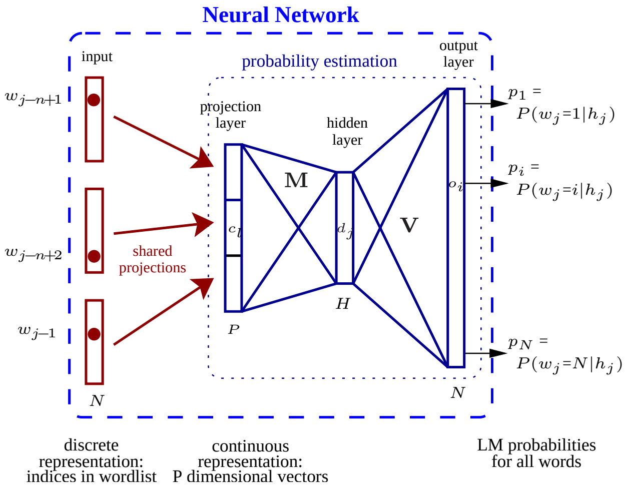

Figure 2: Architecture of the continuous space LM. h_j denotes the context $w_{j-n+1}, \ldots, w_{j-1}$. P is the size of one projection and H,N is the size of the hidden and output layer respectively. When short-lists are used the size of the output layer is much smaller than the size of the vocabulary.

$$P(w_j = i|h_j) \qquad \forall i \in [1, N] \tag{3}$$

where N is the size of the vocabulary. The input uses the so-called 1-of-n coding, i.e., the ith unit of the vocabulary is coded by setting the ith element of the vector to 1 and all the other elements to 0. The ith line of the $N \times P$ dimensional projection matrix corresponds to the continuous representation of the ith unit. Let us denote c_l these projections, d_j the hidden layer activities, o_i the outputs, p_i their softmax normalization, and m_{jl}, b_j, v_{ij} and k_i the hidden and output layer weights and the corresponding biases. Using these notations, the neural network performs the following operations:

$$d_j = \tanh\left(\sum_l m_{jl}\, c_l + b_j\right) \tag{4}$$

$$o_i = \sum_j v_{ij}\, d_j + k_i \tag{5}$$

$$p_i = e^{o_i} \;/\; \sum_{r=1}^{N} e^{o_r} \tag{6}$$

The value of the output neuron p_i corresponds directly to the probability $P(w_j{=}i|h_j)$.

Training is performed with the standard back-propagation algorithm minimizing the following error function:

$$E = \sum_{i=1}^{N} t_i \, log \, p_i + \beta \left(\sum_{jl} m_{jl}^2 + \sum_{ij} v_{ij}^2 \right) \qquad (7)$$

where t_i denotes the desired output, i.e., the probability should be 1.0 for the next unit in the training sentence and 0.0 for all the other ones. The first part of this equation is the cross-entropy between the output and the target probability distributions, and the second part is a regularization term that aims to prevent the neural network from over-fitting the training data (weight decay). The parameter β has to be determined experimentally. Training is done using a re-sampling algorithm as described in (Schwenk, 2007).

It can be shown that the outputs of a neural network trained in this manner converge to the posterior probabilities. Therefore, the neural network directly minimizes the perplexity on the training data. Note also that the gradient is back-propagated through the projection-layer, which means that the neural network learns the projection of the units onto the continuous space that is best for the probability estimation task.

In general, the complexity to calculate one probability with this basic version of the neural network n-gram model is dominated by the dimension of the output layer since the size of the vocabulary (10k to 64k) is usually much larger than the dimension of the hidden layer (200 to 500). Therefore, in previous applications of the continuous space n-gram model, the output was limited to the s most frequent units, s ranging between 2k and 12k (Schwenk, 2007). This is called a short-list.

	Sents	Words
Train (bitexts)	20k	155.4/166.3k
Dev	489	5.2k
Eval	500	6k

Table 1: Available data in the *supplied resources* of the 2006 IWSLT evaluation.

4 Experimental Evaluation

In this work we report results on the *Basic Traveling Expression Corpus* (BTEC) as used in the 2006 evaluations of the international workshop on spoken language translation (IWSLT). This corpus consists of typical sentences from phrase books for tourists in several languages (Takezawa et al., 2002). We report results on the supplied development corpus of 489 sentences and the official test set of the IWSLT’06 evaluation. The main measure is the BLEU score, using seven reference translations. The scoring is case insensitive and punctuations are ignored. Details on the available data are summarized in Table 1. We concentrated first on the translation from Italian to English. All participants in the IWSLT evaluation achieved much better performances for this language pair than for the other considered translation directions. This makes it more difficult to achieve additional improvements.

A non-monotonic search was performed following a local reordering named in Section 2, setting $m = 5$ and $j = 3$. Also we used histogram pruning in the decoder, i.e. the maximum number of hypotheses in a stack is limited to 50.

4.1 Language-dependent preprocessing

Italian contracted prepositions have been separated into preposition + article, such as ’alla’→’a la’, ’degli’→’di gli’ or ’dallo’→’da lo’, among others.

4.2 Model training

The training and development data for the bilingual back-off and neural network translation model were created as follows. Given the alignment of the training parallel corpus, we perform a unique segmentation of each parallel sentence following the criterion of unfolded segmentation seen in Section 2. This segmentation is used in a sequence as training text for building the language model. As an example, given the alignment and the unfold extraction of Figure 1, we obtain the following training sentence:

<s> how_long#cuánto does#NULL last#dura the#el flight#vuelo </s>

The reference bilingual trigram back-off translation model was trained on these bilingual tuples using the SRI LM toolkit (Stolcke, 2002). Different smoothing techniques were tried, and best results were obtained using Good-Turing discounting.

The neural network approach was trained on exactly the same data. A context of two tuples was used (trigram model). The training corpus contains about 21,500 different bilingual tuples. We decided to limit the output of the neural network to the 8k most frequent tuples (short-list). This covers about 90% of the requested tuple n-grams in the training data.

Similar to previous applications, the neural network is not used alone but interpolation is performed to combine several n-gram models. First of all, the neural network and the reference back-off model are interpolated together - this always improved performance since both seem to be complementary. Second, four neural networks with different sizes of the continuous representation were trained and interpolated together. This usually achieves better generalization behavior than training one larger neural network. The interpolation coefficients were calculated by optimizing perplexity on the development data, using an EM procedure. The obtained values are 0.33 for the back-off translation model and about 0.16 for each neural network model respectively. This interpolation is used in all our experiments. For the sake of simplicity we will still call this the continuous space translation model.

Each network was trained independently using early stopping on the development data. Convergence was achieved after about 10 iterations through the training data (less than 20 minutes of processing on a standard Linux machine). The other parameters are as follows:

- Context of two tuples (trigram)
- The dimension of the continuous representation of the tuples were $c =$120,140,150 and 200,
- The dimension of the hidden layer was set to $P = 200$,
- The initial learning rate was 0.005 with an exponential decay,
- The weight decay coefficient was set to $\beta = 0.00005$.

N-gram models are usually evaluated using perplexity on some development data. In our case, i.e. using bilingual tuples as basic units ("words"), it is less obvious if perplexity is a useful measure. Nevertheless, we provide these numbers for completeness. The perplexity on the development data of the trigram back-off translation model is 227.0. This could be reduced to 170.4 using the neural network. It is also very informative to analyze the n-gram hit-rates of the back-off model on the development data: 10% of the probability requests are actually a true trigram, 40% a bigram and about 49% are finally estimated using unigram probabilities. This means that only a limited amount of phrase context is used in the standard N-gram-based translation model. This makes this an ideal candidate to apply the continuous space model since probabilities are interpolated for all possible contexts and never backed-up to shorter contexts.

4.3 Results and analysis

The incorporation of the neural translation model is done using n-best list. Each hypothesis is composed of a sequence of bilingual tuples and the corresponding scores of all the feature functions. Figure 3 shows an example of such an n-best list. The neural trigram translation model is used to replace the scores of the trigram back-off translation model. This is followed by a re-optimization of the coefficients of all feature functions, i.e. maximization of the BLEU score on the development data using the numerical optimization tool CONDOR (Berghen and Bersini, 2005). An alternative would be to add a feature function and to combine both translation models under the log-linear model framework, using maximum BLEU training.

Another open question is whether it might by better to already use the continuous space translation model during decoding. The continuous space model has a much higher complexity than a back-off n-gram. However, this can be heavily optimized when rescoring n-best lists, i.e. by grouping together all calls in the whole n-best list with the same context, resulting in only one forward pass through the neural network. This is more difficult to perform when the continuous space translation model is used during decoding. Therefore, this was not investigated in this work.

spiacente#sorry tutto_occupato#it_’s_full
spiacente#i_’m_sorry tutto_occupato#it_’s_full
spiacente#i_’m_afraid tutto_occupato#it_’s_full
spiacente#sorry tutto#all occupato#busy
spiacente#sorry tutto#all occupato#taken

Figure 3: Example of sentences in the n-best list of bilingual tuples. The special character ’#’ is used to separate the source and target sentence words. Several words in one tuple a grouped together using ’_.’

In all our experiments 1000-best lists were used. In order to evaluate the quality of these n-best lists, an oracle trigram back-off translation model was build on the development data. Rescoring the n-best lists with this translation model resulted in an increase of the BLEU score of about 10 points (see Table 2). While there is an decrease of about 6% for the position dependent word error rate (mWER), a smaller change in the position independent word error rate was observed (mPER). This suggests that most of the alternative translation hypothesis result in word reorderings and not in many alternative word choices. This is one of the major drawbacks of phrase- and N-gram-based translation systems: only translations observed in the training data can be used. There is no generalization to new phrase pairs.

	Back-off	Oracle	**Neural**
BLEU	42.34	52.45	**43.87**
mWER	41.6%	35.6%	**40.3%**
mPER	31.5%	28.2%	**30.7%**

Table 2: Comparison of different N-gram-translation models on the development data.

When the 1000-best lists are rescored with the neural network translation model the BLEU score increases by 1.5 points (42.34 to 43.87). Similar improvements were observed in the word error rates (see Table 2). For comparison, a 4-gram back-off translation model was also built, but no change of the BLEU score was observed. This suggests that careful smoothing is more important than increasing the context when estimating the translation probabilities in an N-gram-based statistical machine translation system.

In previous work, we have investigated the use of the neural network approach to modeling the target language for the IWSLT task (Schwenk et al., 2006). We also applied this technique to this improved N-gram-based translation system. In our implementation, the neural network target 4-gram language model gives an improvement of 1.3 points BLEU on the development data (42.34 to 43.66), in comparison to 1.5 points for the neural translation model (see Table 3).

	Back-off TM+LM	neural TM	neural LM	**neural TM+LM**
BLEU	42.34	43.87	43.66	**44.83**

Table 3: Combination of a neural translation model (TM) and a neural language model (LM). BLEU scores on the development data.

The neural translation and target language model were also applied to the test data, using of course the same feature function coefficients as for the development data. The results are given in Table 4 for all the official measures of the IWSLT evaluation. The new smoothing method of the translation probabilities achieves improvement in all measures. It gives also an additional gain (again in all measures) when used together with a neural target language model. Surprisingly, neural TM and neural LM improvements almost add up: when both techniques are used together, the BLEU scores increases by 1.5 points (36.97 → 38.50). Remember that the reference N-gram-based translation system already uses a local reordering approach.

	Back-off TM+LM	neural TM	neural LM	**neural TM+LM**
BLEU	36.97	37.21	38.04	**38.50**
mWER	48.10	**47.42**	47.83	47.61
mPER	38.21	38.07	37.26	**37.12**
NIST	8.3	8.3	8.6	**8.7**
Meteor	63.16	63.40	64.70	**65.20**

Table 4: Test set scores for the combination of a neural translation model (TM) and a neural language model (LM).

5 Discussion

Phrase-based approaches are the de-facto standard in statistical machine translation. The phrases are extracted automatically from the word alignments of parallel texts, and the different possible translations of a phrase are weighted using relative frequency. This can be problematic when the data is sparse. However, there seems to be little work on possible improvements of the relative frequency estimates by some smoothing techniques. It is today common practice to use additional feature functions like IBM-1 scores to obtain some kind of smoothing (Och et al., 2004; Koehn et al., 2003; Zens and Ney, 2004), but better estimation of the phrase probabilities is usually not addressed.

An alternative way to represent phrases is to define bilingual tuples. Smoothing, and context dependency, is obtained by using an n-gram model on these tuples. In this work, we have extended this approach by using a new smoothing technique that operates on a continuous representation of the tuples. Our method is distinguished by two characteristics: better estimation of the numerous unseen n-grams, and a **discriminative** estimation of the tuple probabilities. Results are provided on the BTEC task of the 2006 IWSLT evaluation for the translation direction Italian to English. This task provides very limited amount of resources in comparison to other tasks. Therefore, new techniques must be deployed to take the best advantage of the limited resources. We have chosen the Italian to English task because it is challenging to enhance a good quality translation task (over 40 BLEU percentage). Using the continuous space model for the **translation** and **target** language model, an improvement of 2.5 BLEU on the development data and 1.5 BLEU on the test data was observed.

Despite these encouraging results, we believe that additional research on improved estimation of probabilities in N-gram- or phrase-based statistical machine translation systems is needed. In particular, the problem of **generalization** to new translations seems to be promising to us. This could be addressed by the so-called factored phrase-based model as implemented in the Moses decoder (Koehn et al., 2007). In this approach words are decomposed into several factors. These factors are translated and a target phrase is generated. This model could be complemented by a factored continuous tuple N-gram. Factored word language models were already successfully used in speech recognition (Bilmes and Kirchhoff, 2003; Alexandrescu and Kirchhoff, 2006) and an extension to machine translation seems to be promising.

The described smoothing method was explicitly developed to tackle the data sparseness problem in tasks like the BTEC corpus. It is well known from language modeling that careful smoothing is less important when large amounts of data are available. We plan to investigate whether this also holds for smoothing of the probabilities in phrase- or tuple-based statistical machine translation systems.

Abstract

Morphological analysis and disambiguation are crucial stages in a variety of natural language processing applications, especially when languages with complex morphology are concerned. We present a system which disambiguates the output of a morphological analyzer for Hebrew. It consists of several simple classifiers and a module which combines them under linguistically motivated constraints. We investigate a number of techniques for combining the predictions of the classifiers. Our best result, 91.44% accuracy, reflects a 25% reduction in error rate compared with the previous state of the art.

1 Introduction

Morphological analysis and disambiguation are crucial pre-processing steps for a variety of natural language processing applications, from search and information extraction to machine translation. For languages with complex morphology these are non-trivial processes. This paper presents a morphological disambiguation module for Hebrew which uses a sophisticated combination of classifiers to rank the analyses produced by a morphological analyzer. This work has a twofold contribution: first, our system achieves over 91% accuracy on the full disambiguation task, reducing the error rate of the previous state of the art by 25%. More generally, we explore several ways for combining the predictions of simple classifiers under constraints; the insight gained from these experiments will be useful for other applications of machine learning to complex (morphological and other) problems.

In the remainder of this section we discuss the complexity of Hebrew morphology, the challenge of morphological disambiguation and related work. We describe our methodology in Section 2: we use basic, naïve classifiers (Section 3) to predict some components of the analysis, and then combine them in several ways (Section 4) to predict a consistent result. We analyze the errors of the system in Section 5 and conclude with suggestions for future work.

1.1 Linguistic background

Hebrew morphology is rich and complex.[1] The major word formation machinery is root-and-pattern, and inflectional morphology is highly productive and consists of prefixes, suffixes and circumfixes. Nouns, adjectives and numerals inflect for number (singular, plural and, in rare cases, also dual) and gender (masculine or feminine). In addition, all these three types of nominals have two phonologically and morphologically distinct forms, known as the *absolute* and *construct* states. In the standard orthography approximately half of the nominals appear to have identical forms in both states, a fact which substantially increases the ambiguity. In addition, nominals take possessive pronominal suffixes which inflect for number, gender and person.

Verbs inflect for number, gender and person (first, second and third) and also for a combination of tense and aspect/mood, referred to simply as ‘tense’ below. Verbs can also take pronominal suffixes, which are interpreted as direct objects, and in some cases can also take nominative pronominal suffixes. A peculiarity of Hebrew verbs is that the participle form

[1] To facilitate readability we use a straight-forward transliteration of Hebrew using ASCII characters, where the characters (in Hebrew alphabetic order) are: abgdhwzxviklmnsypcqr$t.

Proceedings of the 2007 Joint Conference on Empirical Methods in Natural Language Processing and Computational Natural Language Learning, pp. 439–447, Prague, June 2007. ©2007 Association for Computational Linguistics

can be used as present tense, but also as a noun or an adjective.

These matters are complicated further due to two sources: first, the standard Hebrew orthography leaves most of the vowels unspecified. On top of that, the script dictates that many particles, including four of the most frequent prepositions, the definite article, the coordinating conjunction and some subordinating conjunctions, all attach to the words which immediately follow them. When the definite article *h* is prefixed by one of the prepositions *b*, *k* or *l*, it is assimilated with the preposition and the resulting form becomes ambiguous as to whether or not it is definite. For example, *bth* can be read either as *b+th* “in tea” or as *b+h+th* “in the tea”. Thus, the form *$bth* can be read as an inflected stem (the verb “capture”, third person singular feminine past), as *$+bth* “that+field”, *$+b+th* “that+in+tea”, *$+b+h+th* “that in the tea”, *$bt+h* “her sitting” or even as *$+bt+h* “that her daughter”.

An added complexity stems from the fact that there are two main standards for the Hebrew script: one in which vocalization diacritics, known as *niqqud* “dots”, decorate the words, and another in which the dots are missing, and other characters represent some, but not all of the vowels. Most of the texts in Hebrew are of the latter kind; unfortunately, different authors use different conventions for the undotted script. Thus, the same word can be written in more than one way, sometimes even within the same document. This fact adds significantly to the degree of ambiguity.

Our departure point in this work is HAMSAH (Yona and Wintner, 2007), a wide coverage, linguistically motivated morphological analyzer of Hebrew, which was recently re-implemented in Java and made available from the Knowledge Center for Processing Hebrew (`http://mila.cs.technion.ac.il/`). The output that HAMSAH produces for the form *$bth* is illustrated in Table 1. In general, it includes the part of speech (POS) as well as sub-category, where applicable, along with several POS-dependent features such as number, gender, tense, nominal state, definitness, etc.

1.2 The challenge of disambiguation

Identifying the correct morphological analysis of a given word in a given context is an important and non-trivial task. Unlike POS tagging, the task does not involve assigning an analysis to words which the analyzer does not recognize. However, selecting an analysis immediately induces a POS tagging for the target word (by projecting the analysis on the POS coordinate). Our main contribution in this work is a system that solves this problem with high accuracy.

Compared with POS tagging of English, morphological disambiguation of Hebrew is a much more complex endeavor due to the following factors:

Segmentation A single token in Hebrew can actually be a sequence of more than one lexical item. For example, analysis 4 of Table 1 (*$+b+h+th* “that+in+the+tea”) corresponds to the tag sequence IN+IN+DT+NN.

Large tagset The number of different tags in a language such as Hebrew (where the POS, morphological features and prefix and suffix particles are considered) is huge. HAMSAH produces 22 different parts of speech, some with subcategories; 6 values for the number feature (including disjunctions of values), 4 for gender, 5 for person, 7 for tense and 3 for nominal state. Possessive pronominal suffixes can have 15 different values, and prefix particle sequences can theoretically have hundreds of different forms. While not all the combinations of these values are possible, we estimate the number of possible analyses to be in the thousands.

Ambiguity Hebrew is highly ambiguous: HAMSAH outputs on average approximately 2.64 analyses per word token. Oftentimes two or more alternative analyses share the same part of speech, and in some cases two or more analyses are completely identical, except for their lexeme (see analyses 7 and 8 in Table 1). Morphological disambiguation of Hebrew is hence closer to the problem of word sense disambiguation than to standard POS tagging.

Anchors, which are often function words, are almost always morphologically ambiguous in Hebrew. These include most of the high-frequency forms. Many of the function words which help boost the performance of English POS tagging are actually prefix particles which add to the ambiguity in Hebrew.

#	Lexical ID	lexeme	POS	Num	Gen	Per	Ten	Stat	Def	Pref	Suf
1	17280	*$bt*	noun	sing	fem	N/A	N/A	abs	no		h

Table 1: The analyses of the form *$bth*

Word order in Hebrew is freer than in English.

1.3 Related work

The idea of using short context for morphological disambiguation dates back to Choueka and Lusignan (1985). Levinger et al. (1995) were the first to apply it to Hebrew, but their work was hampered by the lack of annotated corpora for training and evaluation. The first work which uses stochastic contextual information for morphological disambiguation in Hebrew is Segal (1999): texts are analyzed using the morphological analyzer of Segal (1997); then, each word in a text is assigned its most likely analysis, defined by probabilities computed from a small tagged corpus. In the next phase the system corrects its own decisions by using short context (one word to the left and one to the right of the target word). The corrections are also automatically learned from the tagged corpus (using transformation-based learning). In the last phase, the analysis is corrected by the results of a syntactic analysis of the sentence. The reported results are excellent: 96.2% accuracy. More reliable tests, however, reveal accuracy of 85.5% only (Lemberski, 2003, page 85). Furthermore, the performance of the program is unacceptable (the reported running time on "two papers" is thirty minutes).

Bar-Haim et al. (2005) use Hidden Markov Models (HMMs) to implement a segmenter and a tagger for Hebrew. The main innovation of this work is that it models word-segments (morphemes: prefixes, stem and suffixes), rather than full words. The accuracy of this system is 90.51% for POS tagging (a tagset of 21 POS tags is used) and 96.74% for segmentation (which is defined as identifying all prefixes, including a possibly assimilated definite article). As noted above, POS tagging does not amount to full morphological disambiguation.

Recently, Adler and Elhadad (2006) presented an unsupervised, HMM-based model for Hebrew morphological disambiguation, using a morphological analyzer as the only resource. A morpheme-based model learns both segmentation and tagging in parallel from a large (6M words) un-annotated corpus. Reported results are 92.32% for POS tagging and 88.5% for full morphological disambiguation. We refer to this result as the state of the art and use the same data for evaluation.

A supervised approach to morphological disambiguation of *Arabic* is given by Habash and Rambow (2005), who use two corpora of 120K words each to train several classifiers. Each morphological feature is predicted separately and then combined into a full disambiguation result. The accuracy of the disambiguator is 94.8%-96.2% (depending on the test corpus). Note, however, the high baseline of each classifier (96.6%-99.9%, depending on the classifier) and the full disambiguation task (87.3%-92.1%, depending on the corpus). We use a very similar approach below, but we experiment with more sophisticated methods for combining simple classifiers to induce a coherent prediction.

2 Methodology

For training and evaluation, we use a corpus of approximately 90,000 word tokens, consisting of newspaper texts, which was automatically analyzed using HAMSAH and then manually annotated (Elhadad et al., 2005). Annotation consists simply of selecting the correct analysis produced by the analyzer, or an indication that no such analysis exists. When the analyzer does not produce the correct analysis, it is added manually. This is the exact setup of the experiments reported by Adler and Elhadad (2006).

Table 2 lists some statistics of the corpus, and a histogram of analyses is given in Table 3. Table 4 lists the distribution of POS in the corpus.

Tokens	89347
Types	23947
Tokens with no correct analysis	8218
Tokens with no analysis	130
Degree of ambiguity	2.64

Table 2: Statistics of training corpus

# analyses	# tokens	# analyses	# tokens
1	38468	7	1977
2	15480	8	1309
3	11194	9	785
4	9934	10	622
5	5341	11	238
6	3472	>12	397

Table 3: Histogram of analyses

In all the experiments described in this paper we use SNoW (Roth, 1998) as the learning environment, with *winnow* as the update rule (using *perceptron* yielded very similar results). SNoW is a multi-class classifier that is specifically tailored for learning in domains in which the potential number of information sources (features) taking part in decisions is very large, of which NLP is a principal example. It works by learning a sparse network of linear functions over the feature space. SNoW has already been used successfully as the learning vehicle in a large collection of natural language related tasks and compared favorably with other classifiers (Punyakanok and Roth, 2001; Florian, 2002). Typically, SNoW is used as a classifier, and predicts using a winner-take-all mechanism over the activation values of the target classes. However, in addition to the prediction, it provides a reliable confidence level in the prediction, which enables its use in an inference algorithm that combines predictors to produce a coherent inference.

POS	# tokens	% tokens
Noun	25836	28.92
Punctuation	13793	15.44
Proper Noun	7238	8.10

Modal	5	0.01

Table 4: POS frequencies

Following Daya et al. (2004) and Habash and Rambow (2005), we approach the problem of morphological disambiguation as a complex classification task. We train a classifier for each of the attributes that can contribute to the disambiguation of the analyses produced by HAMSAH (e.g., POS, tense, state). Each classifier predicts a small set of possible values and hence can be highly accurate. In particular, the basic classifiers do not suffer from problems of data sparseness. Of course, each simple classifier cannot fully disambiguate the output of HAMSAH, but it does induce a ranking on the analyses (see Table 6 below for the level of ambiguity which remains after each simple classifier is applied). Then, we combine the outcomes of the simple classifiers to produce a consistent ranking which induces a linear order on the analyses.

For evaluation we consider only the words that have at least one correct analysis in the annotated corpus. *Accuracy* is defined as the ratio between the number of words classified correctly and the total number of words in the test corpus that have a correct analysis. The *remaining level of ambiguity* is defined as the average number of analyses per word whose score is equal to the score of the top ranked analysis. This is greater than 1 only for the simple classifiers, where more than one analysis can have the same tag. In all the experiments we perform 10-fold cross-validation runs and report the average of the 10 runs, both on the entire corpus and on a subset of the corpus in which we only test on words which do *not* occur in the training corpus.

The *baseline* tag of the token w_i is the most prominent tag of all the occurrences of w_i in the corpus. The baseline for the combination is the most prominent analysis of all the occurrences of w_i in the corpus. If w_i does not occur in the corpus, we back off and select the most prominent tag in the corpus independently of the word w_i. For the combination baseline, we select the analysis of the most prominent lexical ID, chosen from the list of all possible lexical IDs of w_i. If there is more than one possible value, one top-ranking value is chosen at random.

3 Basic Classifiers

The simple classifiers are all built in the same way. They are trained on feature vectors that are generated from the output of the morphological analyzer, and tested on a clean output of the same analyzer. We defined several classifiers for the attributes of the morphological analyses. Since some attributes do not apply to all the analyses, we add a value of 'N/A' for the inapplicable attributes. An annotated corpus was needed in all those classifiers for training. We list the basic classifiers below.

POS 22 values (only 18 in our corpus), see Table 4.

Gender 'Masculine', 'Feminine', 'Masculine and feminine', 'N/A'.

Number 'Singular', 'Plural', 'Dual', 'N/A'.

Person 'First', 'Second', 'Third', 'N/A'.

Tense 'Past', 'Present', 'Participle', 'Future', 'Imperative', 'Infinitive', 'Bare Infinitive', 'N/A'.

Definite Article 'Def', 'indef', 'N/A'. Identifies also implicit (assimilated) definiteness.

Status 'Absolute', 'Construct' and 'N/A'.

Segmentation Predicts the number of letters which are prefix particles. Possible values are [0-6], 6 being the length of longest possible prefix sequence. Does not identify implicit definiteness.

Has properties A binary classifier which distinguishes between atomic POS categories (e.g., conjunction or negation) and categories whose words have attributes (such as nouns or verbs).

Each word in the training corpus induces features that are generated for itself and its immediate neighbors, using the output of the morphological analyzer. For each word in the window, we generate the following features: POS, number, gender, person, tense, state, definiteness, prefixes (where each possible prefix is a binary feature), suffix (binary: is there word suffixed?), number/gender/person of suffix, surface form, lemma, conjunction of the surface form and the POS, conjunction of the POS and the POS of prefixes and suffixes, and some disjunctions of POS. The total number of features for each example is huge (millions), but feature vectors are very sparse.

The simple classifiers can be configured in several ways. First, the size of the window around the target word had to be determined, and we experimented with several sizes, up to ± 3 words. Another issue is feature generation. It is straight-forward during training, but during evaluation and testing the feature extractor is presented only with the set of analyses produced by HAMSAH for each word, and has no access to the *correct* analysis. We experimented with two methods for tackling this problem: produce the *union* of all possible values for each feature; or select a single analysis, the baseline one, for each word, and generate only the features induced by this analysis. While this problem is manifested only during testing, it impacts also the training procedure, and so we experimented with feature generation at training using the correct analysis, the union of the analyses or the baseline analysis. The results of the experiments for the POS classifier are shown in Table 5. The best configuration uses a window of two words before and one word after the target word. For both testing and training we generate features using the baseline analysis.

With this setup, the accuracy of all the classifiers is shown in Table 6. We report results on two tasks: the entire test corpus; and words in the test corpus which do not occur in the training corpus, a much harder task. We list the *accuracy*, remaining level of *ambiguity* and reduction in error rate *ERR*, com-

Training	Testing	1 - 2	2 - 1	2 - 2	1 - 3	3 - 1	2 - 3	3 - 2	3 - 3
correct	baseline	91.37	91.53	91.69	91.55	91.69	91.83	91.75	**92.01**

pared with the baseline.

4 Combination of Classifiers

Given a set of simple classifiers, we now investigate various ways for combining their predictions. These predictions may be contradicting (for example, the POS classifier can predict ‘noun’ while the tense classifier predicts ‘past’), and we use the constraints imposed by the morphological analyzer to enforce a consistent analysis.

First, we define a naïve combination along the lines of Habash and Rambow (2005). The scores assigned by the simple classifiers (except segmentation, for which we use the baseline) to each analysis are accumulated, and the score of the complete analysis is their sum (experiments with different weights to the various classifiers proved futile). Even after the combination, the remaining level of ambiguity is 1.05; in ambiguous cases back off to the baseline analysis, and then choose at random one of the top-ranking analyses. The result of the combination is shown in Table 7.

	baseline	classifier	ERR
All words	86.11	**90.26**	29.88
Unseen words	67.53	78.52	33.85

Table 7: Results of the naïve combination

Next, we define a hierarchical combination in which we try to incorporate more linguistic knowledge pertaining to the dependencies between the classifiers. As a pre-processing step we classify the target word to one of two groups, using the *has properties* classifier. Then, we predict the main POS of the target word, and take this prediction to be true; we then apply only the subset of the other classifiers that are relevant to the main POS.

The results of the hierarchical combination are shown in Table 8. As can be seen, the hierarchical combination performs worse than the naïve one. We conjecture that this is because the hierarchical combination does not fully disambiguate, and a random top-ranking analysis is chosen more often than in the case of the naïve combination.

	naïve	hierarchical	ERR
All words	90.26	89.61	—
Unseen words	78.52	78.08	—

Table 8: Results of the hierarchial combination

The combination of independent classifiers under the constraints imposed by the possible morphological analyses is intended to capture context-dependent constraints on possible sequences of analyses. Such constraints are stochastic in nature, but linguistic theory tells us that several *hard* (deterministic) constraints also exist which rule out certain sequences of otherwise possible analyses. We now explore the utility of implementing such constraints to filter out linguistically impossible sequences.

Using several linguistic sources, we defined a set of constraints, each of which is a linguistically impossible sequence of analyses (all sequences are of length 2, although in principle longer ones could have been defined). We then checked the annotated corpus for violations of these constraints; we used the corpus to either verify the correctness of a constraint or further refine it (or abandon it altogether, in some cases). We then re-iterated the process with the new set of constraints.

The result was a small set of six constraints which are not violated in our annotated corpus. We used the constraints to rule out some of the paths defined by the possible outcomes of the morphological analyzer on a sequence of words. Each of the constraints below contributes a non-zero reduction in the error rate of the disambiguation module.The (slightly simplified) constraints are:

1. A verb in any tense but present cannot be followed by the genitive preposition '$l' (of).

2. A preposition with no attached pronomial suffix must be followed by a nominal phrase. This rule is relaxed for some prepositions which can be followed by the prefix '$'.

3. The preposition 'at' must be followed by a definite nominal phrase.

4. Construct-state words must be followed by a nominal phrase.

5. A sequence of two verbs is only allowed if: one of them is the verb 'hih' (be); one of them has a prefix; the second is infinitival; or the first is imperative and the second is in future tense.

6. A non-numeral quantifier must be followed by either a nominal phrase or a punctuation.

Imposing the linguistically motivated constraints on the classifier combination improved the results to some extent, as depicted in Table 9. The best results are obtained when the constraints are applied to the hierarchical combination.

5 Error analysis

We conducted extensive error analysis of both the simple classifiers and the combination module. The analysis was performed over one fold of the annotated corpus (8933 tokens). Table 10 depicts, for some classifiers, a subset of the confusion matrix: it lists the *correct* tag, the *chosen*, or predicted, tag, the number of occurrences of the specific error and the total number of errors made by the classifier.

classifier	correct	chosen	#	total
has props	yes	no	110	167
	no	yes	57	
segmentation	1	0	160	176
state	const	abs	154	412
definiteness	def	indef	98	300

Table 10: Simple classifiers, confusion matrix

Several patterns can be observed in Table 10. The 'has properties' classifier is biased towards predicting 'yes' instead of 'no'. The 'segmentation' classifier, which predicts the length of the prefix, also displays a clear bias. In almost 90% of its errors it predicts no prefix instead of a prefix of length one. 'Status' and 'definiteness' are among the weakest classifiers, biased towards the default.

Other classifiers make more sporadic types of errors. Of particular interest is the POS classifier. Here, when adjectives are mis-predicted, they are predicted as nouns. This can be explained by the morphological similarity of the two categories, and in particular by the similar syntactic contexts in which they occur. Similarly, almost 90% of mis-predicted verbs are predicted to be either nouns

	naïve	naïve + consts	ERR	hier.	hier. + cons	ERR
All words	90.26	90.90	6.57	89.61	**91.44**	17.61
Unseen words	78.52	79.56	4.84	78.08	81.74	16.70

Table 9: Accuracy results of various combination architectures. *ERR* is reduction in error rate due to the hard constraints. The best results are obtained using the hierarchical combination with hard constraints.

or adjectives, probably resulting from present-tense verbs in the training corpus which, in Hebrew, have similar distribution to nouns and adjectives.

The analysis of errors in the combination is more interesting. On the entire corpus, the disambiguator makes 7927 errors. Of those, 1476 (19%) are errors in which the correct analysis differs from the chosen one *only* in the value of the 'state' feature. Furthermore, in 1341 of the errors (17%) the system picks the correct analysis up to the value of 'definiteness'; of those, 1275 (16% of the errors) are words in which the definite article is assimilated in a preposition. In sum, many of the errors seem to be in the real tough cases.

6 Conclusions

Morphological disambiguation of Hebrew is a difficult task which involves, in theory, thousands of possible tags. We reconfirm the results of Daya et al. (2004) and Habash and Rambow (2005), which show that decoupling complex morphological tasks into several simple tasks improves the accuracy of classification. Our best result, 91.44% accuracy, reflects a reduction of 25% in error rate compared to the previous state of the art (Adler and Elhadad, 2006), and almost 40% compared to the baseline. We also show that imposing few context-dependent constraints on possible sequences of analyses improves the accuracy of the disambiguation. The disambiguation module will be made available through the Knowledge Center for Processing Hebrew (`http://mila.cs.technion.ac.il/`).

We believe that these results can be further improved in various ways. The basic classifiers can benefit from more detailed feature engineering and careful tuning of the parameters of the learning environment. There are various ways in which interrelated classifiers can be combined; we only explored three here. Using other techniques, such as inference-based training, in which the feature generation for training is done step by step, using information inferred in the previous step, is likely to yield better accuracy. We also believe that further linguistic exploration, based on deeper error analysis, will result in more hard constraints which can reduce the error rate of the combination module. Finally, we are puzzled by the differences between Hebrew and Arabic (for which the baseline and the current state of the art are significantly higher) on this task. We intend to investigate the linguistic sources for this puzzle in the future.

Acknowledgements

We are extremely grateful to Dan Roth for his continuing support and advise; to Meni Adler for providing the annotated corpus; to Dalia Bojan and Alon Itai for the implementation of the morphological analyzer; to Yariv Louck for the implementation of the deterministic constraints; to Nurit Melnik for help with error analysis; and to Yuval Nardi his help with statistical analysis. Thanks are due to Ido Dagan, Alon Lavie and Michael Elhadad for useful comments and advise. Abstract

We present a new approach to automatic summarization based on neural nets, called NetSum. We extract a set of features from each sentence that helps identify its importance in the document. We apply novel features based on news search query logs and Wikipedia entities. Using the RankNet learning algorithm, we train a pair-based sentence ranker to score every sentence in the document and identify the most important sentences. We apply our system to documents gathered from CNN.com, where each document includes highlights and an article. Our system significantly outperforms the standard baseline in the ROUGE-1 measure on over 70% of our document set.

1 Introduction

Automatic summarization was first studied almost 50 years ago by Luhn (Luhn, 1958) and has continued to be a steady subject of research. Automatic summarization refers to the creation of a shortened version of a document or cluster of documents by a machine, see (Mani, 2001) for details. The summary can be an abstraction or extraction. In an abstract summary, content from the original document may be paraphrased or generated, whereas in an extract summary, the content is preserved in its original form, i.e., sentences. Both summary types can involve sentence compression, but abstracts tend to be more condensed. In this paper, we focus on producing fully automated single-document extract summaries of newswire articles.

To create an extract, most automatic systems use linguistic and/or statistical methods to identify key words, phrases, and concepts in a sentence or across single or multiple documents. Each sentence is then assigned a score indicating the strength of presence of key words, phrases, and so on. Sentence scoring methods utilize both purely statistical and purely semantic features, for example as in (Vanderwende et al., 2006; Nenkova et al., 2006; Yih et al., 2007).

Recently, machine learning techniques have been successfully applied to summarization. The methods include binary classifiers (Kupiec et al., 1995), Markov models (Conroy et al., 2004), Bayesian methods (Daumé III and Marcu, 2005; Aone et al., 1998), and heuristic methods to determine feature weights (Schiffman, 2002; Lin and Hovy, 2002). Graph-based methods have also been employed (Erkan and Radev, 2004a; Erkan and Radev, 2004b; Mihalcea, 2005; Mihalcea and Tarau, 2005; Mihalcea and Radev, 2006).

In 2001–02, the Document Understanding Conference (DUC, 2001), issued the task of creating a 100-word summary of a single news article. The best performing systems (Hirao et al., 2002; Lal and Ruger, 2002) used various learning and semantic-based methods, although no system could outperform the baseline with statistical significance (Nenkova, 2005). After 2002, the single-document summarization task was dropped.

In recent years, there has been a decline in studies on automatic single-document summarization, in part because the DUC task was dropped, and in part because the task of single-document extracts may be counterintuitively more difficult than multi-

Proceedings of the 2007 Joint Conference on Empirical Methods in Natural Language Processing and Computational Natural Language Learning, pp. 448–457, Prague, June 2007. ©2007 Association for Computational Linguistics

document summarization (Nenkova, 2005). However, with the ever-growing internet and increased information access, we believe single-document summarization is essential to improve quick access to large quantities of information. Recently, CNN.com (CNN.com, 2007a) added “Story Highlights” to many news articles on its site to allow readers to quickly gather information on stories. These highlights give a brief overview of the article and appear as 3–4 related sentences in the form of bullet points rather than a summary paragraph, making them even easier to quickly scan.

Our work is motivated by both the addition of highlights to an extremely visible and reputable online news source, as well as the inability of past single-document summarization systems to outperform the extremely strong baseline of choosing the first n sentences of a newswire article as the summary (Nenkova, 2005). Although some recent systems indicate an improvement over the baseline (Mihalcea, 2005; Mihalcea and Tarau, 2005), statistical significance has not been shown. We show that by using a neural network ranking algorithm and third-party datasets to enhance sentence features, our system, NetSum, can outperform the baseline with statistical significance.

Our paper is organized as follows. Section 2 describes our two studies: summarization and highlight extraction. We describe our dataset in detail in Section 3. Our ranking system and feature vectors are outlined in Section 4. We present our evaluation measure in Section 5. Sections 6 and 7 report on our results on summarization and highlight extraction, respectively. We conclude in Section 8 and discuss future work in Section 9.

2 Our Task

In this paper, we focus on single-document summarization of newswire documents. Each document consists of three highlight sentences and the article text. Each highlight sentence is human-generated, but is based on the article. In Section 4 we discuss the process of matching a highlight to an article sentence. The output of our system consists of purely extracted sentences, where we do not perform any sentence compression or sentence generation. We leave such extensions for future work.

We develop two separate problems based on our document set. First, can we extract three sentences that best “match” the highlights as a whole? In this task, we concatenate the three sentences produced by our system into a single summary or *block*, and similarly concatenate the three highlight sentences into a single summary or *block*. We then compare our system’s block against the highlight block. Second, can we extract three sentences that best “match” the three highlights, such that ordering is preserved? In this task, we produce three sentences, where the first sentence is compared against the first highlight, the second sentence is compared against the second highlight, and the third sentence is compared against the third highlight. Credit is not given for producing three sentences that match the highlights, but are out of order. The second task considers ordering and compares sentences on an individual level, whereas the first task considers the three chosen sentences as a summary or block and disregards sentence order. In both tasks, we assume the title has been seen by the reader and will be listed above the highlights.

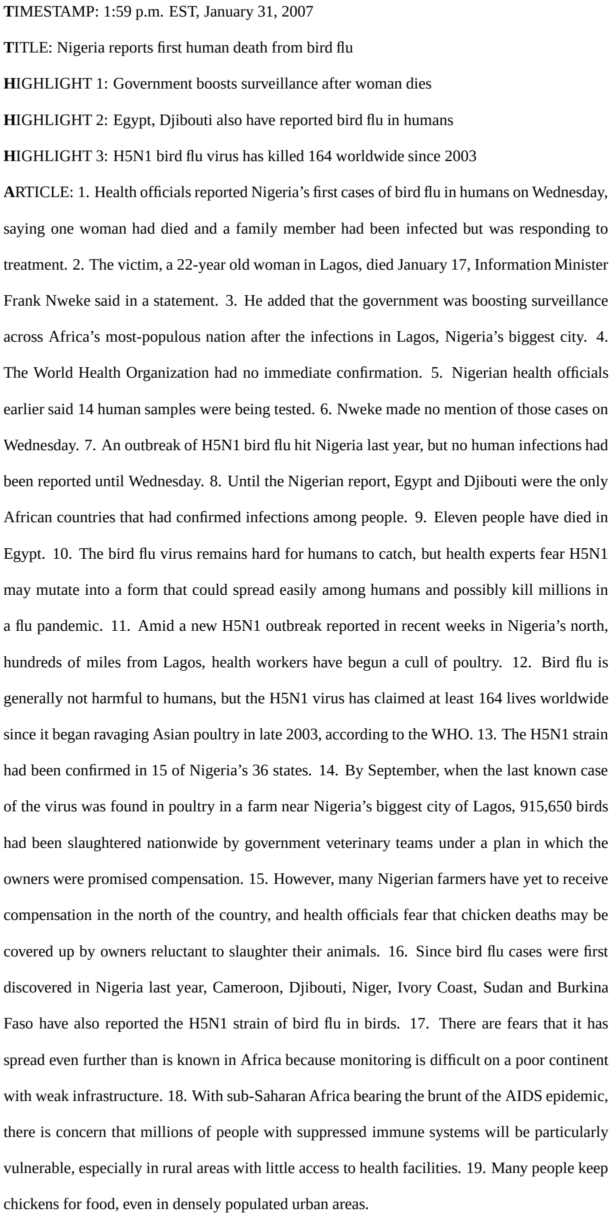
3 Evaluation Corpus

Our data consists of 1365 news documents gathered from CNN.com (CNN.com, 2007a). Each document was extracted by hand, where a maximum of 50 documents per day were collected. The documents were hand-collected on consecutive days during the month of February.

Each document includes the title, timestamp, story highlights, and article text. The timestamp on articles ranges from December 2006 to February 2007, since articles remain posted on CNN.com for up to several months. The story highlights are human-generated from the article text. The number of story highlights is between 3–4. Since all articles include at least 3 story highlights, we consider only the task of extracting three highlights from each article.

4 Description of Our System

Our goal is to extract three sentences from a single news document that best match various characteristics of the three document highlights. One way to identify the best sentences is to rank the sentences



TIMESTAMP: 1:59 p.m. EST, January 31, 2007

TITLE: Nigeria reports first human death from bird flu

HIGHLIGHT 1: Government boosts surveillance after woman dies

HIGHLIGHT 2: Egypt, Djibouti also have reported bird flu in humans

HIGHLIGHT 3: H5N1 bird flu virus has killed 164 worldwide since 2003

ARTICLE: 1. Health officials reported Nigeria's first cases of bird flu in humans on Wednesday, saying one woman had died and a family member had been infected but was responding to treatment. 2. The victim, a 22-year old woman in Lagos, died January 17, Information Minister Frank Nweke said in a statement. 3. He added that the government was boosting surveillance across Africa's most-populous nation after the infections in Lagos, Nigeria's biggest city. 4. The World Health Organization had no immediate confirmation. 5. Nigerian health officials earlier said 14 human samples were being tested. 6. Nweke made no mention of those cases on Wednesday. 7. An outbreak of H5N1 bird flu hit Nigeria last year, but no human infections had been reported until Wednesday. 8. Until the Nigerian report, Egypt and Djibouti were the only African countries that had confirmed infections among people. 9. Eleven people have died in Egypt. 10. The bird flu virus remains hard for humans to catch, but health experts fear H5N1 may mutate into a form that could spread easily among humans and possibly kill millions in a flu pandemic. 11. Amid a new H5N1 outbreak reported in recent weeks in Nigeria's north, hundreds of miles from Lagos, health workers have begun a cull of poultry. 12. Bird flu is generally not harmful to humans, but the H5N1 virus has claimed at least 164 lives worldwide since it began ravaging Asian poultry in late 2003, according to the WHO. 13. The H5N1 strain had been confirmed in 15 of Nigeria's 36 states. 14. By September, when the last known case of the virus was found in poultry in a farm near Nigeria's biggest city of Lagos, 915,650 birds had been slaughtered nationwide by government veterinary teams under a plan in which the owners were promised compensation. 15. However, many Nigerian farmers have yet to receive compensation in the north of the country, and health officials fear that chicken deaths may be covered up by owners reluctant to slaughter their animals. 16. Since bird flu cases were first discovered in Nigeria last year, Cameroon, Djibouti, Niger, Ivory Coast, Sudan and Burkina Faso have also reported the H5N1 strain of bird flu in birds. 17. There are fears that it has spread even further than is known in Africa because monitoring is difficult on a poor continent with weak infrastructure. 18. With sub-Saharan Africa bearing the brunt of the AIDS epidemic, there is concern that millions of people with suppressed immune systems will be particularly vulnerable, especially in rural areas with little access to health facilities. 19. Many people keep chickens for food, even in densely populated urban areas.

Figure 1: Example document containing highlights and article text. Sentences are numbered by their position. Article is from (CNN.com, 2007b).

using a machine learning approach, for example as in (Hirao et al., 2002). A train set is labeled such that the labels identify the best sentences. Then a set of features is extracted from each sentence in the train and test sets, and the train set is used to train the system. The system is then evaluated on the test set. The system learns from the train set the distribution of features for the best sentences and outputs a ranked list of sentences for each document. In this paper, we rank sentences using a neural network algorithm called RankNet (Burges et al., 2005).

4.1 RankNet

From the labels and features for each sentence, we train a model that, when run on a test set of sentences, can infer the proper ranking of sentences in a document based on information gathered during training about sentence characteristics. To accomplish the ranking, we use RankNet (Burges et al., 2005), a ranking algorithm based on neural networks.

RankNet is a pair-based neural network algorithm used to rank a set of inputs, in this case, the set of sentences in a given document. The system is trained on pairs of sentences (S_i, S_j), such that S_i should be ranked higher or equal to S_j. Pairs are generated between sentences in a single document, not across documents. Each pair is determined from the input labels. Since our sentences are labeled using ROUGE (see Section 4.3), if the ROUGE score of S_i is greater than the ROUGE score of S_j, then (S_i, S_j) is one input pair. The cost function for RankNet is the probabilistic cross-entropy cost function. Training is performed using a modified version of the back propagation algorithm for two layer nets (Le Cun et al., 1998), which is based on optimizing the cost function by gradient descent. A similar method of training on sentence pairs in the context of multi-document summarization was recently shown in (Toutanova et al., 2007).

Our system, NetSum, is a two-layer neural net trained using RankNet. To speed up the performance of RankNet, we implement RankNet in the framework of LambdaRank (Burges et al., 2006). For details, see (Burges et al., 2006; Burges et al., 2005). We experiment with between 5 and 15 hidden nodes and with an error rate between 10^{-2} and 10^{-7}.

We implement 4 versions of NetSum. The first version, NetSum(b), is trained for our first summarization problem (b indicates block). The pairs are generated using the maximum ROUGE scores l_1 (see Section 4.3). The other three rankers are trained to identify the sentence in the document that best matches highlight n. We train one ranker, NetSum(n), for each highlight n, for $n = 1, 2, 3$, resulting in three rankers. NetSum(n) is trained using pairs generated from the $l_{1,n}$ ROUGE scores between sentence S_i and highlight H_n (see Section 4.3).

4.2 Matching Extracted to Generated Sentences

In this section, we describe how to determine which sentence in the document best matches a given highlight. Choosing three sentences most similar to the three highlights is very challenging since the highlights include content that has been gathered across sentences and even paragraphs, and furthermore include vocabulary that may not be present in the text. Jing showed, for 300 news articles, that 19% of human-generated summary sentences contain no matching article sentence (Jing, 2002). In addition, only 42% of the summary sentences match the content of a single article sentence, where there are still semantic and syntactic transformations between the summary sentence and article sentence.. Since each highlight is human generated and does not exactly match any one sentence in the document, we must develop a method to identify how closely related a highlight is to a sentence. We use the ROUGE (Lin, 2004b) measure to score the similarity between an article sentence and a highlight sentence. We anticipate low ROUGE scores for both the baseline and NetSum due to the difficulty of finding a single sentence to match a highlight.

4.3 ROUGE

Recall-Oriented Understudy for Gisting Evaluation (Lin, 2004b), known as ROUGE, measures the quality of a model-generated summary or sentence by comparing it to a "gold-standard", typically human-generated, summary or sentence. It has been shown that ROUGE is very effective for measuring both single-document summaries and single-document headlines (Lin, 2004a).

ROUGE-N is a N-gram recall between a model-generated summary and a reference summary. We use ROUGE-N, for $N = 1$, for labeling and evaluation of our model-generated highlights.[1] ROUGE-1 and ROUGE-2 have been shown to be statistically similar to human evaluations and can be used with a single reference summary (Lin, 2004a). We have only one reference summary, the set of human-generated highlights, per document. In our work, the reference summary can be a single highlight sentence or the highlights as a block. We calculate ROUGE-N as

$$\frac{\sum_{gram_j \in R \cap S_i} Count(gram_j)}{\sum_{gram_j \in R} Count(gram_j)}, \tag{1}$$

where R is the reference summary, S_i is the model-generated summary, and N is the length of the N-gram $gram_j$.[2] The numerator cannot excede the number of N-grams (non-unique) in R.

We label each sentence S_i by its ROUGE-1 score. For the first problem of matching the highlights as a block, we label each S_i by l_1, the maximum ROUGE-1 score between S_i and each highlight H_n, for $n = 1, 2, 3$, given by $l_1 = \max_n(R(S_i, H_n))$.

For the second problem of matching three sentences to the three highlights individually, we label each sentence S_i by $l_{1,n}$, the ROUGE-1 score between S_i and H_n, given by $l_{1,n} = R(S_i, H_n)$. The ranker for highlight n, NetSum(n), is passed samples labeled using $l_{1,n}$.

4.4 Features

RankNet takes as input a set of samples, where each sample contains a label and feature vector. The labels were previously described in Section 4.3. In this section, we describe each feature in detail and motivate in part why each feature is chosen. We generate 10 features for each sentence S_i in each document, listed in Table 1. Each feature is chosen to identify characteristics of an article sentence that may match those of a highlight sentence. Some of the features such as position and N-gram frequencies are commonly used for scoring. Sentence scoring based on

[1] We use an implementation of ROUGE that does not perform stemming or stopword removal.

[2] ROUGE is typically used when the length of the reference summary is equal to length of the model-generated summary. Our reference summary and model-generated summary are different lengths, so there is a slight bias toward longer sentences.

Symbol	Feature Name
$F(S_i)$	Is First Sentence
$Pos(S_i)$	Sentence Position
$SB(S_i)$	SumBasic Score
$SB_b(S_i)$	SumBasic Bigram Score
$Sim(S_i)$	Title Similarity Score
$NT(S_i)$	Average News Query Term Score
$NT_+(S_i)$	News Query Term Sum Score
$NT_r(S_i)$	Relative News Query Term Score
$WE(S_i)$	Average Wikipedia Entity Score
$WE_+(S_i)$	Wikipedia Entity Sum Score

Table 1: Features used in our model.

sentence position, terms common with the title, appearance of keyword terms, and other cue phrases is known as the Edmundsonian Paradigm (Edmundson, 1969; Alfonesca and Rodriguez, 2003; Mani, 2001). We use variations on these features as well as a novel set of features based on third-party data.

Typically, news articles are written such that the first sentence summarizes the article. Thus, we include a binary feature $F(S_i)$ that equals 1 if S_i is the first sentence of the document: $F(S_i) = \delta_{i,1}$, where δ is the Kronecker delta function. This feature is used only for NetSum(b) and NetSum(1).

We include sentence position since we found in empirical studies that the sentence to best match highlight H_1 is on average 10% down the article, the sentence to best match H_2 is on average 20% down the article, and the sentence to best match H_3 is 31% down the article.[3] We calculate the position of S_i in document D as

$$Pos(S_i) = \frac{i}{\ell}, \tag{2}$$

where $i = \{1, \ldots, \ell\}$ is the sentence number and ℓ is the number of sentences in D.

We include the SumBasic score (Nenkova et al., 2006) of a sentence to estimate the importance of a sentence based on word frequency. We calculate the SumBasic score of S_i in document D as

$$SB(S_i) = \frac{\sum_{w \in S_i} p(w)}{|S_i|}, \tag{3}$$

where $p(w)$ is the probability of word w and $|S_i|$ is the number of words in sentence S_i. We calculate $p(w)$ as $p(w) = \frac{Count(w)}{|D|}$, where $Count(w)$ is the number of times word w appears in document D and $|D|$ is the number of words in document D. Note that the score of a sentence is the average probability of a word in the sentence.

We also include the SumBasic score over bigrams, where w in Eq 3 is replaced by bigrams and we normalize by the number of bigrams in S_i.

We compute the similarity of a sentence S_i in document D with the title T of D as the relative probability of title terms $t \in T$ in S_i as

$$Sim(S_i) = \frac{\sum_{t \in S_i} p(t)}{|S_i|}, \tag{4}$$

where $p(t) = \frac{Count(t)}{|T|}$ is the number of times term t appears in T over the number of terms in T.

The remaining features we use are based on third-party data sources. Previously, third-party sources such as WordNet (Fellbaum, 1998), the web (Jagalamudi et al., 2006), or click-through data (Sun et al., 2005) have been used as features. We propose using news query logs and Wikipedia entities to enhance features. We base several features on query terms frequently issued to Microsoft's news search engine http://search.live.com/news, and entities[4] found in the online open-source encyclopedia Wikipedia (Wikipedia.org, 2007). If a query term or Wikipedia entity appears frequently in a CNN document, then we assume highlights should include that term or entity since it is important on both the document and global level. Sentences containing query terms or Wikipedia entities therefore contain important content. We confirm the importance of these third-party features in Section 7.

We collected several hundred of the most frequently queried terms in February 2007 from the news query logs. We took the daily top 200 terms for 10 days. Our hypothesis is that a sentence with a higher number of news query terms should be a better candidate highlight. We calculate the average probability of news query terms q in S_i as

$$NT(S_i) = \frac{\sum_{q \in S_i} p(q)}{|q \in S_i|}, \tag{5}$$

[3] Though this is not always the case, as the sentence to match H_2 precedes that to match H_1 in 22.03% of documents, and the sentence to match H_3 precedes that to match H_2 in 29.32% of and precedes that to match H_1 in 28.81% of documents.

[4] We define an entity as a title of a Wikipedia page.

where $p(q)$ is the probability of a news term q and $|q \in S_i|$ is the number of news terms in S_i. $p(q) = \frac{Count(q)}{|q \in D|}$, where $Count(q)$ is the number of times term q appears in D and $|q \in D|$ is the number of news query terms in D.

We also include the sum of news query terms in S_i, given by $NT_+(S_i) = \sum_{q \in S_i} p(q)$, and the relative probability of news query terms in S_i, given by $NT_r(S_i) = \frac{\sum_{q \in S_i} p(q)}{|S_i|}$.

We perform term disambiguation on each document using an entity extractor (Cucerzan, 2007). Terms are disambiguated to a Wikipedia entity only if they match a surface form in Wikipedia. Wikipedia surface forms are terms that disambiguate to a Wikipedia entity and link to a Wikipedia page with the entity as its title. For example, "WHO" and "World Health Org." both refer to the World Health Organization, and should disambiguate to the entity "World Health Organization". Sentences in CNN document D that contain Wikipedia entities that frequently appear in CNN document D are considered important. We calculate the average Wikipedia entity score for S_i as

$$WE(S_i) = \frac{\sum_{e \in S_i} p(e)}{|e \in S_i|}, \tag{6}$$

where $p(e)$ is the probability of entity e, given by $p(e) = \frac{Count(e)}{|e \in D|}$, where $Count(e)$ is the number of times entity e appears in CNN document D and $|e \in D|$ is the total number of entities in CNN document D.

We also include the sum of Wikipedia entities, given by $WE_+(S_i) = \sum_{e \in S_i} p(e)$.

Note that all features except position features are a variant of SumBasic over different term sets. All features are computed over sentences where every word has been lowercased and punctuation has been removed after sentence breaking. We examined using stemming, but found stemming to be ineffective.

5 Evaluation

We evaluate the performance of NetSum using ROUGE and by comparing against a baseline system. For the first summarization task, we compare against the baseline of choosing the first three sentences as the block summary. For the second highlights task, we compare NetSum(n) against the baseline of choosing sentence n (to match highlight n). Both tasks are novel in attempting to match highlights rather than a human-generated summary.

We consider ROUGE-1 to be the measure of importance and thus train our model on ROUGE-1 (to optimize ROUGE-1 scores) and likewise evaluate our system on ROUGE-1. We list ROUGE-2 scores for completeness, but do not expect them to be substantially better than the baseline since we did not directly optimize for ROUGE-2.[5]

For every document in our corpus, we compare NetSum's output with the baseline output by computing ROUGE-1 and ROUGE-2 between the highlight block and NetSum and between the highlight block and the block of sentences. Similarly, for each highlight, we compute ROUGE-1 and ROUGE-2 between highlight n and NetSum(n) and between highlight n and sentence n, for $n = 1, 2, 3$. For each task, we calculate the average ROUGE-1 and ROUGE-2 scores of NetSum and of the baseline. We also report the percent of documents where the ROUGE-1 score of NetSum is equal to or better than the ROUGE-1 score of the baseline.

We perform all experiments using five-fold cross-validation on our dataset of 1365 documents. We divide our corpus into five random sets and train on three combined sets, validate on one set, and test on the remaining set. We repeat this procedure for every combination of train, validation, and test sets. Our results are the micro-averaged results on the five test sets. For all experiments, Table 3 lists the statistical tests performed and the significance of performance differences between NetSum and the baseline at 95% confidence.

6 Results: Summarization

We first find three sentences that, as a block, best match the three highlights as a block. NetSum(b) produces a ranked list of sentences for each document. We create a block from the top 3 ranked sentences. The baseline is the block of the first 3 sentences of the document. A similar baseline outper-

[5] NetSum can directly optimize for any measure by training on it, such as training on ROUGE-2 or on a weighted sum of ROUGE-1 and ROUGE-2 to optimize both. Thus, ROUGE-2 scores could be further improved. We leave such studies for future work.

System	Av. ROUGE-1	Av. ROUGE-2
Baseline	0.4642 ± 0.0084	0.1726 ± 0.0064
NetSum(b)	**0.4956** ± 0.0075	0.1775 ± 0.0066

Table 2: Results on summarization task with standard error at 95% confidence. Bold indicates significance under paired tests.

	ROUGE-1			ROUGE-2		
System	1	2	3	1	2	3
NetSum(b)	**x**	**x**	**x**	**x**	o	o
NetSum(1)	**x**	**x**	**x**	o	o	o
NetSum(2)	**x**	**x**	**x**	**x**	o	**x**
NetSum(3)	**x**	**x**	**x**	**x**	**x**	**x**

Table 3: Paired tests for statistical significance at 95% confidence between baseline and NetSum performance; 1: McNemar, 2: Paired t-test, 3: Wilcoxon signed-rank. "**x**" indicates pass, "o" indicates fail. Since our studies are pair-wise, tests listed here are more accurate than error bars reported in Tables 2–5.

forms all previous systems for news article summarization (Nenkova, 2005) and has been used in the DUC workshops (DUC, 2001).

For each block produced by NetSum(b) and the baseline, we compute the ROUGE-1 and ROUGE-2 scores of the block against the set of highlights as a block. For 73.26% of documents, NetSum(b) produces a block with a ROUGE-1 score that is equal to or better than the baseline score. The two systems produce blocks of equal ROUGE-1 score for 24.69% of documents. Under ROUGE-2, NetSum(b) performs equal to or better than the baseline on 73.19% of documents and equal to the baseline on 40.51% of documents.

Table 2 shows the average ROUGE-1 and ROUGE-2 scores obtained with NetSum(b) and the baseline. NetSum(b) produces a higher quality block on average for ROUGE-1.

Table 4 lists the sentences in the block produced by NetSum(b) and the baseline block, for the articles shown in Figure 1. The NetSum(b) summary achieves a ROUGE-1 score of 0.52, while the baseline summary scores only 0.36.

System	Sent. #	ROUGE-1
Baseline	S_1, S_2, S_3	0.36
NetSum(b)	S_1, S_7, S_{15}	**0.52**

Table 4: Block results for the block produced by NetSum(b) and the baseline block for the example article. ROUGE-1 scores computed against the highlights as a block are listed.

7 Results: Highlights

Our second task is to extract three sentences from a document that best match the three highlights in order. To accomplish this, we train NetSum(n) for each highlight $n = 1, 2, 3$. We compare NetSum(n) with the baseline of picking the nth sentence of the document. We perform five-fold cross-validation across our 1365 documents. Our results are reported for the micro-average of the test results. For each highlight n produced by both NetSum(n) and the baseline, we compute the ROUGE-1 and ROUGE-2 scores against the nth highlight.

We expect that beating the baseline for $n = 1$ is a more difficult task than for $n = 2$ or 3 since the first sentence of a news article typically acts as a summary of the article and since we expect the first highlight to summarize the article. NetSum(1), however, produces a sentence with a ROUGE-1 score that is equal to or better than the baseline score for 93.26% of documents. The two systems produce sentences of equal ROUGE-1 scores for 82.84% of documents. Under ROUGE-2, NetSum(1) performs equal to or better than the baseline on 94.21% of documents.

Table 5 shows the average ROUGE-1 and ROUGE-2 scores obtained with NetSum(1) and the baseline. NetSum(1) produces a higher quality sentence on average under ROUGE-1.

The content of highlights 2 and 3 is typically from later in the document, so we expect the baseline to not perform as well in these tasks. NetSum(2) outperforms the baseline since it is able to identify sentences from further down the document as important. For 77.73% of documents, NetSum(2) produces a sentence with a ROUGE-1 score that is equal to or better than the score for the baseline. The two systems produce sentences of equal ROUGE-1 score for 33.92% of documents. Under ROUGE-2, NetSum(2) performs equal to or better than the baseline

System	Av. ROUGE-1	Av. ROUGE-2
Baseline(1)	0.4343 ± 0.0138	0.1833 ± 0.0095
NetSum(1)	**0.4478** ± 0.0133	0.1857 ± 0.0085
Baseline(2)	0.2451 ± 0.0128	0.0814 ± 0.0106
NetSum(2)	**0.3036** ± 0.0117	**0.0877** ± 0.0107
Baseline(3)	0.1707 ± 0.0103	0.0412 ± 0.0069
NetSum(3)	**0.2603** ± 0.0133	**0.0615** ± 0.0075

Table 5: Results on ordered highlights task with standard error at 95% confidence. Bold indicates significance under paired tests.

System	Sent. #	ROUGE-1
Baseline	S_1	0.167
NetSum(1)	S_1	0.167
Baseline	S_2	0.111
NetSum(2)	S_1	**0.556**
Baseline	S_3	0.000
NetSum(3)	S_{15}	**0.400**

Table 6: Highlight results for highlight n produced by NetSum(n) and highlight n produced by the baseline for the example article. ROUGE-1 scores computed against highlight n are listed.

84.84% of the time. For 81.09% of documents, NetSum(3) produces a sentence with a ROUGE-1 score that is equal to or better than the score for the baseline. The two systems produce sentences of equal ROUGE-1 score for 28.45% of documents. Under ROUGE-2, NetSum(3) performs equal to or better than the baseline 89.91% of the time.

Table 5 shows the average ROUGE-1 and ROUGE-2 scores obtained for NetSum(2), NetSum(3), and the baseline. Both NetSum(2) and NetSum(3) produce a higher quality sentence on average under both measures.

Table 6 gives highlights produced by NetSum(n) and the highlights produced by the baseline, for the article shown in Figure 1. The NetSum(n) highlights produce ROUGE-1 scores equal to or higher than the baseline ROUGE-1 scores.

In feature ablation studies, we confirmed that the inclusion of news-based and Wikipedia-based features improves NetSum's peformance. For example, we removed all news-based and Wikipedia-based features in NetSum(3). The resulting performance moderately declined. Under ROUGE-1, the baseline produced a better highlight on 22.34% of documents, versus only 18.91% when using third-party features. Similarly, NetSum(3) produced a summary of equal or better ROUGE-1 score on only 77.66% of documents, compared to 81.09% of documents when using third-party features. In addition, the average ROUGE-1 score dropped to 0.2182 and the average ROUGE-2 score dropped to 0.0448. The performance of NetSum with third-party features over NetSum without third-party features is statistically significant at 95% confidence. However, NetSum still outperforms the baseline without third-party features, leading us to conclude that RankNet and simple position and term frequency features contribute the maximum performance gains, but increased ROUGE-1 and ROUGE-2 scores are a clear benefit of third-party features.

8 Conclusions

We have presented a novel approach to automatic single-document summarization based on neural networks, called NetSum. Our work is the first to use both neural networks for summarization and third-party datasets for features, using Wikipedia and news query logs. We have evaluated our system on two novel tasks: 1) producing a block of highlights and 2) producing three ordered highlight sentences. Our experiments were run on previously unstudied data gathered from CNN.com. Our system shows remarkable performance over the baseline of choosing the first n sentences of the document, where the performance difference is statistically significant under ROUGE-1.

9 Future Work

An immediate future direction is to further explore feature selection. We found third-party features beneficial to the performance of NetSum and such sources can be mined further. In addition, feature selection for each NetSum system could be performed separately since, for example, highlight 1 has different characteristics than highlight 2.

In our experiments, ROUGE scores are fairly low because a highlight rarely matches the content of a single sentence. To improve NetSum's performance, we must consider extracting content across sentence boundaries. Such work requires a system to produce abstract summaries. We hope to incorporate sentence simplification and sentence splicing and merging in a future version of NetSum.

Another future direction is the identification of "hard" and "easy" inputs. Although we report average ROUGE scores, such measures can be misleading since some highlights are simple to match and some are much more difficult. A better system evaluation measure would incorporate the difficulty of the input and weight reported results accordingly.

Abstract

Textual records of business-oriented conversations between customers and agents need to be analyzed properly to acquire useful business insights that improve productivity. For such an analysis, it is critical to identify appropriate textual segments and expressions to focus on, especially when the textual data consists of complete transcripts, which are often lengthy and redundant. In this paper, we propose a method to identify important segments from the conversations by looking for changes in the accuracy of a categorizer designed to separate different business outcomes. We extract effective expressions from the important segments to define various viewpoints. In text mining a viewpoint defines the important associations between key entities and it is crucial that the correct viewpoints are identified. We show the effectiveness of the method by using real datasets from a car rental service center.

1 Introduction

"Contact center" is a general term for customer service centers, help desks, and information phone lines. Many companies operate contact centers to sell their products, handle customer issues, and address product-related and services-related issues. In contact centers, analysts try to get insights for improving business processes from stored customer contact data. Gigabytes of customer contact records are produced every day in the form of audio recordings of speech, transcripts, call summaries, email, etc. Though analysis by experts results in insights that are very deep and useful, such analysis usually covers only a very small (1-2%) fraction of the total call volume and yet requires significant workload. The demands for extracting trends and knowledge from the whole text data collection by using text mining technology, therefore, are increasing rapidly.

In order to acquire valuable knowledge through text mining, it is generally critical to identify important expressions to be monitored and compared within the textual data. For example, given a large collection of contact records at the contact center of a manufacturer, the analysis of expressions for products and expressions for problems often leads to business value by identifying specific problems in a specific product. If 30% of the contact records with expressions for a specific product such as "ABC" contain expressions about a specific trouble such as "cracked", while the expressions about the same trouble appear in only 5% of the contact records for similar products, then it should be a clue that the product "ABC" may actually have a crack-related problem. An effective way to facilitate this type of analysis is to register important expressions in a lexicon such as "ABC" and "cracked" as associated respectively with their categories such as "product" and "problem" so that the behavior of terms in the same category can be compared easily. It is actually one of the most important steps of text mining to identify such relevant expressions and their categories that can potentially lead to some valuable insights. A failure in this step often leads to a failure in the text mining. Also, it has been considered an artistic task that requires highly experienced consul-

Proceedings of the 2007 Joint Conference on Empirical Methods in Natural Language Processing and Computational Natural Language Learning, pp. 458–467, Prague, June 2007.

tants to define such categories, which are often described as the viewpoint for doing the analysis, and their corresponding expressions through trial and error.

In this paper, we propose a method to identify important segments of textual data for analysis from full transcripts of conversations. Compared to the written summary of a conversation, a transcription of an entire conversation tends to be quite lengthy and contains various forms of redundancy. Many of the terms appearing in the conversation are not relevant for specific analysis. For example, the terms for greeting such as “Hello” and “Welcome to (Company A)” are unlikely to be associated with specific business results such as purchased-or-not and satisfied-or-not, especially because the conversation is transcribed without preserving the nonverbal moods such as tone of voice, emotion etc. Thus it is crucial to identify key segments and notable expressions within conversations for analysis to acquire valuable insights.

We exploit the fact that business conversations follow set patterns such as an opening followed by a request and the confirmation of details followed by a closing, etc. By taking advantage of this feature of business conversations, we have developed a method to identify key segments and the notable expressions within conversations that tend to discriminate between the business results. Such key segments, the trigger segments, and the notable expressions associated with certain business results lead us to easily understand appropriate viewpoints for analysis.

Application of our method for analyzing nearly one thousand conversations from a rental car reservation office enabled us to acquire novel insights for improving agent productivity and resulted in an actual increase in revenues.

Organization of the Paper: We start by describing the properties of the conversation data used in this paper. Section 3 describes the method for identifying useful viewpoints and expressions that meet the specified purpose. Section 4 provides the results using conversational data. After the discussion in Section 5, we conclude the paper in Section 6.

2 Business-Oriented Conversation Data

We consider business-oriented conversation data collected at contact centers handling inbound telephone sales and reservations. Such business oriented conversations have the following properties.

- Each conversation is a one-to-one interaction between a customer and an agent.
- For many contact center processes the conversation flow is well defined in advance.
- There are a fixed number of outcomes and each conversation has one of these outcomes.

For example, in car rentals, the following conversation flow is pre-defined for the agent. In practice most calls to a car rental center follow this call flow.

- Opening - contains greeting, brand name, name of agent
- Pick-up and return details - agent asks location, dates and times of pick up and return, etc.
- Offering car and rate - agent offers a car specifying rate and mentions applicable special offers.
- Personal details - agent asks for customer’s information such as name, address, etc.
- Confirm specifications - agent recaps reservation information such as name, location, etc.
- Mandatory enquiries - agent verifies clean driving record, valid license, etc.
- Closing - agent gives confirmation number and thanks the customer for calling.

In these conversations the participants speak in turns and the segments can be clearly identified. Figure 1 shows part of a transcribed call.

Each call has a specific outcome. For example, each car rental transaction has one of two call types, reservation or unbooked, as an outcome.

Because the call process is pre-defined, the conversations look similar in spite of having different results. In such a situation, finding the differences in the conversations that have effects on the outcomes is very important, but it is very expensive and difficult to find such unknown differences by human analysis. We show that it is possible to define proper viewpoints and corresponding expressions leading to insights on how to change the outcomes of the calls.

```
AGENT: Welcome to CarCompanyA. My name is Albert.  How may I
help you?
.........
AGENT: Allright may i know the location you want to pick the
car from.
CUSTOMER: Aah ok I need it from SFO.
AGENT: For what date and time.
.........
AGENT: Wonderful so let me see ok mam so we have a 12 or 15
passenger van avilable on this location on those dates and
for that your estimated total for those three dates just
300.58$ this is with Taxes with surcharges and with free
unlimited free milleage.
.........
AGENT : alright mam let me recap the dates you want to pick
it up from SFO on 3rd August and drop it off on august 6th in
LA alright
CUSTOMER : and one more questions Is it just in states or
could you travel out of states
.........
AGENT : The confirmation number for your booking is 221 384.
CUSTOMER : ok ok Thank you
Agent :  Thank you for calling CarCompanyA and you have a
great day good bye
```

3 Trigger Segment Detection and Effective Expression Extraction

In this section, we describe a method for automatically identifying valuable segments and concepts from the data for the user-specified difference analysis. First, we present a model to represent the conversational data. After that we introduce a method to detect the segments where the useful concepts for the analysis appear. Finally, we select useful expressions in each detected trigger segment.

3.1 Data Model

Each conversational data record in the collection D is defined as $\boldsymbol{d}_i$. Each $\boldsymbol{d}_i$ can be seen as a sequence of conversational *turns* in the conversational data, and then $\boldsymbol{d}_i$ can be divided as

$$\boldsymbol{d}_i = \boldsymbol{d}_i^1 + \boldsymbol{d}_i^2 + \cdots + \boldsymbol{d}_i^{M_i}, \qquad (1)$$

where $\boldsymbol{d}_i^k$ is the k-th turn in $\boldsymbol{d}_i$ and M_i is the total number of turns in $\boldsymbol{d}_i$. The $+$ operator in the above equation can be seen as an equivalent of the string concatenation operator. We define $\boldsymbol{d}_i^{\sim j}$ as the portion of $\boldsymbol{d}_i$ from the beginning to turn j. Using the same notation, $\boldsymbol{d}_i^{\sim j} = \boldsymbol{d}_i^1 + \boldsymbol{d}_i^2 + \cdots + \boldsymbol{d}_i^j$. The collection of $\boldsymbol{d}_i^{\sim m_k}$ constitutes the *Chronologically Cumulative Data* up to turn m_k (D_k). D_k is represented as

$$D_k = (\boldsymbol{d}_1^{\sim m_k}, \boldsymbol{d}_2^{\sim m_k}, \ldots, \boldsymbol{d}_n^{\sim m_k}). \qquad (2)$$

Figure 2 shows an image of the data model. We set some m_k and prepare the chronologically cumulative data set as shown in Figure 3. We represent binary mutually exclusive business outcomes such as success and failure resulting from the conversations as "A" and "not A".

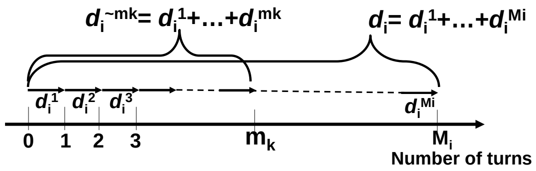

Figure 2: Conversation data model

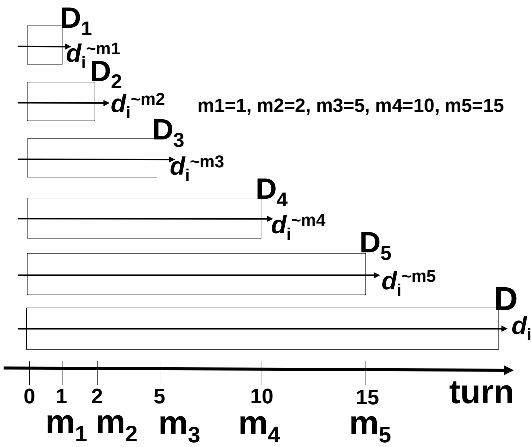

Figure 3: Chronologically cumulative conversational data

3.2 Trigger Segment Detection

Trigger segments can be viewed as portions of the data which have important features which distinguish data of class "A" from data of class "not A".

To detect such segments, we divide each chronologically cumulative data set D_k into two data sets, training data $D_k^{training}$ and test data D_k^{test}. Starting from D_1, for each D_k we trained a classifier using $D_k^{training}$ and evaluated it on D_k^{test}. Using accuracy, the fraction of correctly classified documents, as a metric of performance (Yang and Liu, 1999), we denote the evaluation result of the categorization as $acc(categorizer(D_k))$ for each D_k and plot it along with its turn. Figure 4 shows the effect of gradually increasing the training data for the classification. The distribution of expressions in a business-oriented conversation will change almost synchronously because the call flow is predefined. Therefore $acc(categorizer(D_k))$ will increase if features that contribute to the categorization appear in D_k. In contrast, $acc(categorizer(D_k))$ will decrease if no features that contribute to the categorization are in D_k. Therefore, from the transitions of $acc(categorizer(D_k))$, we can identify the segments with increases as triggers where the features that have an effect on the outcome appear. We denote a trigger segment as $seg(start\, position, end\, position)$. Because the total numbers of turns can be different, we do not detect the last section as a trigger. In Figure 4, $seg(m_1, m_2)$ and $seg(m_4, m_5)$ are triggers. It is important to note that using the cumulative data is key to the detection of trigger segments. Using non-cumulative segment data would give us the categorization accuracy for the features within that segment but would not tell us whether the features of this segment are improving the accuracy or decreasing it. It is this gradient information between segments that is key to identifying trigger segments.

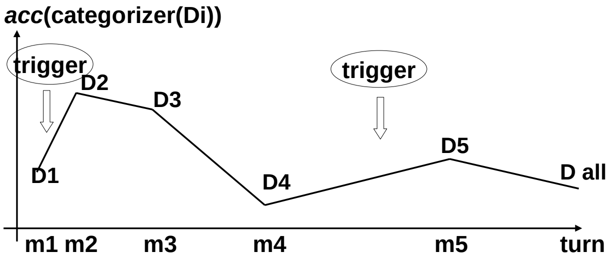

Figure 4: Plot of $acc(categorizer(D_k))$

Many approaches have been proposed for document classification (Yang and Liu, 1999). In this research, however, we are not interested in the classification accuracy itself but in the increase and decrease of the accuracy within particular segments. For example, the greeting, or the particular method of payment may not affect the outcome, but the mention of a specific feature of the product may have an effect on the outcome. Therefore in our research we are interested in identifying the particular portion of the call where this product feature is mentioned, along with its mention, which has an effect on the outcome of the call. In our experiments we used the SVM (Support Vector Machine) classifier (Joachims, 1998), but almost any classifier should work because our approach does not depend on the classification method.

3.3 Effective Expression Extraction

In this section, we describe our method to extract effective expressions from the detected trigger segments.

The effective expressions in D_k are those which are representative in the selected documents and appear for the first time in the trigger segments $seg(m_i, m_j)$. Numerous methods to select features exist (Hisamitsu and Niwa, 2002) (Yang and Pedersen, 1997). We use the χ^2 statistic for each expression in D_k as a representative metric. For the two-by-two contingency table of a expression w and a class "A" shown in Table 1, the χ^2 statistic is calculated as

Table 1: Contingency table for calculating the χ^2 statistic

	# of documents including w	# of documents not including w
A	n_{11}	n_{12}
not-A	n_{21}	n_{22}

$$\chi^2 = \frac{N(n_{11}n_{22} - n_{12}n_{21})^2}{(n_{11}+n_{12})(n_{11}+n_{21})(n_{12}+n_{22})(n_{21}+n_{22})} \quad (3)$$

where N is the number of documents. This statistic can be compared to the χ^2 distribution with one degree of freedom to judge representativeness.

We also want to extract the expressions that have not had an effect on the outcome before D_k. To detect the new expressions in D_k, we define the metric

$$new(w) = \frac{w(D_k)}{\max(w(D_{k-1}), 1)} \Big/ \frac{m_k}{m_{k-1}} \times \mathrm{sign}(w(D_k^A) - w(D_k^{notA})), \quad (4)$$

where $w(D_k)$ is the frequency of expression w in the chronologically cumulative data D_k, $\max(a, b)$ selects the larger value in the arguments, m_k is the number of turns in D_k, $w(D_k^A)$ is the frequency of w in D_k with the outcome of the corresponding data being "A", and $\mathrm{sign}(\cdot)$ is the signum function. When w in class "A" appears in D_k much more frequently than D_{k-1} compared with the ratio of their turns, this metric will be more than 1. We detect significant expressions by considering the combined score $\chi^2(w) \cdot new(w)$. Using this combined score, we can filter out the representative expressions that have already appeared before D_k and distinguish significant expressions that first appear in D_k for each class "A" and "not A".

3.4 Appropriate Viewpoint Selection

In a text mining system, to get an association that leads to a useful insight, we have to define appropriate viewpoints. Viewpoints refer to objects in relation to other objects. In analysis using a conventional text mining system (Nasukawa and Nagano, 2001), the viewpoints are selected based on expressions in user dictionaries prepared by domain experts. We have identified important segments of the conversations by seeing changes in the accuracy of a categorizer designed to segregate different business outcomes. We have also been able to extract effective expressions from these *trigger* segments to define various viewpoints. Hence, viewpoint selection is now based on the trigger segments and effective expressions identified automatically based on specified business outcomes. In the next section we apply our technique to a real life dataset and show that we can successfully select useful viewpoints.

4 Experiments and Results

4.1 Experiment Data and System

We collected 914 recorded calls from the car rental help desk and manually transcribed them. Figure 1 shows part of a call that has been transcribed.

There are three types of calls:

1. **Reservation Calls:** Calls which got *converted*. Here, "converted" means the customer made a reservation for a car. Reserved cars can get *picked-up* or *not picked-up*, so some reserved cars do not eventually get picked-up by customers (no shows and cancellations).

2. **Unbooked Calls:** Calls which did not get converted.

3. **Service Calls:** Customers changing or enquiring about a previous booking.

The distribution of the calls is given in Table 2.

Table 2: Distribution of calls

Unbooked Calls	461
Reservation Calls (Picked-Up)	72
Reservation Calls (Not Picked-Up)	65
Service Calls	326
Total Calls	914

The reservation calls are most important in this context, so we focus on those 137 calls. In the reservation calls, there are two types of outcomes, car picked-up and car not picked-up. All reservation calls look similar in spite of having different outcomes (in terms of pick up). The reservation happens during the call but the pick up happens at a later date. If we can find differences in the conversation that affect the outcome, it is expected that we could improve the agent productivity. Reservation calls follow the pre-defined reservation call flow that we mentioned in Section 2 and it is very difficult to find differences between them manually. In this experiment, by using the proposed method, we try to extract trigger segments and expressions to find viewpoints that affect the outcome of the reservation calls.

For the analysis, we constructed a text mining system for the difference analysis "picked-up" vs. "not picked-up". The experimental system consists of two parts, an information extraction part and a text mining part. In the information extraction part we define dictionaries and templates to identify useful expressions. In the text mining part we define appropriate viewpoints based on the identified expressions to get useful associations leading to useful insights.

4.2 Results of Trigger Segment Detection and Effective Expression Extraction

Based on the pre-defined conversation flow described in Section 2, we set m_1=1, m_2=2, m_3=5, m_4=10, m_5=15, and m_6=20 and prepared $D_1, \ldots, D_6$ and D. The features of $\boldsymbol{d}_i$ consist of nouns, compound nouns, specified noun phrases (e.g. adjective+noun), and verbs. For each D_k we calculated $acc(categorizer(D_k))$ for the classes "picked-up" and "not picked-up." In this process, we use a SVM-based document categorizer (Joachims, 2002). Of the 137 calls, we used 100 calls for training the categorizer and 37 calls for trigger segment detection. Figure 5 shows the results of $acc(categorizer(D_k))$ for picked-up. The accuracy of classification using the data of entire conversations ($acc(categorizer(D))$ is 67.6% but we are trying to detect important segments by considering not the accuracy values themselves but the gradients between segments. From these results, $seg(1, 2)$ and $seg(10, 15)$ are detected as trigger segments. We now know that these segments are highly correlated to the outcome of the call.

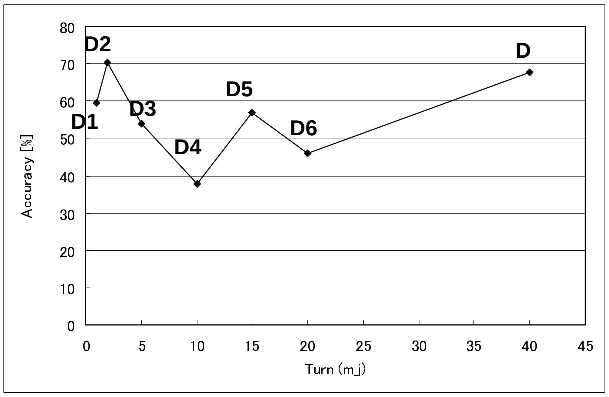

Figure 5: Result of $acc(categorizer(D_k))$

Table 3: Selected expressions in trigger segments

Trigger	Selected expressions	
	pick up	not picked up
$seg(1, 2)$	make, return, tomorrow, day, airport, look, assist, reservation, tonight	rate, check, see want, week
$seg(10, 15)$	number, corporate program, contract, card, have, tax surcharge, just NUMERIC dollars, discount, customer club, good rate, economy	go, impala

For each detected trigger segment, we extract effective expressions in each class using the metric described in Section 3.3. Table 3 shows some expressions with high values for the metric for each trigger. In this table, ”just NUMERIC dollars” is a canonical expression and an expression such as ”just 160 dollars” is mapped to this canonical expression in the information extraction process. From this result, in $seg(1, 2)$, "make", "reservation" are correlated with "pick up" and "rate" and "check" are correlated with "not-picked up". By looking at some documents containing these expressions, we found customer intention phrases such as "would like to make a reservation", "want to check a rate", etc. Therefore, it can be induced that the way a customer starts the call may have an impact on the outcome. From expressions in $seg(10, 15)$, it can be said that discount-related phrases and mentions of the good rates by the agent can have an effect on the outcome.

We can directly apply the conventional methods for representative feature selection to D. The following expressions were selected as the top 20 expressions from whole conversational data by using the χ^2 metric defined in (3).

corporate program, contract, counter, September,
mile, rate, economy, last name,
valid driving license,BRAND NAME, driving,
telephone, midsize, tonight, use, credit, moment,
airline, afternoon

From these results, we see that looking at the call as a whole does not point us to the fact that discount-related phrases, or the first customers-utterance, affect the outcome. Detecting trigger segments and extracting important expressions from each trigger segment are key to identifying subtle differences between very similar looking calls that have entirely opposite outcomes.

4.3 Results of Text Mining Analysis using Selected Viewpoints and Expressions

From the detected segments and expressions we determined that the customer's first utterance along with discount phrases and value selling phrases affected the call outcomes. Under these hypotheses, we prepared the following semantic categories.

- Customer intention at start of call: From the customer's first utterance, we extract the following intentions based on the patterns.
  - strong start: *would like to make a booking, need to pick up a car, . . .*
  - weak start: *would like to check the rates, want to know the rate for vans, . . .*

  Under our hypotheses, the customer with a strong start has the intention of booking a car and we classify such a customer as a **booking_customer**. The customer with a weak start usually just wants to know the rates and is classified as a **rates_customer**.
- discount-related phrases: *discount, corporate program, motor club, buying club . . .* are registered into the domain dictionary as discount-related phrases.
- value selling phrases: we extract phrases mentioning good rates and good vehicles by matching patterns related to such utterances.
  - mentions of good rates: *good rate, wonderful price, save money, just need to pay this low amount, . . .*
  - mentions of good vehicles: *good car, fantastic car, latest model, . . .*

Using these three categories, we tried to find insights to improve agent productivity.

Table 4 shows the result of two-dimensional association analysis for 137 reservation calls. This table shows the association between customer types based on customer intention at the start of a call and pick up information. From these results, 67% (47 out of 70) of the booking_customers picked up the reserved car and only 35% (13 out of 37) of the rates_customers picked it up. This supports our hypothesis and means that pick up is predictable from the customer's first or second utterance.

Table 4: Association between customer types and pick up information

Customer types extracted from texts based on customer intent at start of call	Pick up information	
	pick up	not-picked up
booking_customer (w/ strong start) (70)	47	23
rates_customer (w/ weak start) (37)	13	24

It was found that cars booked by rates_customers tend to be "not picked up," so if we can find any actions by agents that convert such customers into "pick up," then the revenue will improve. In the booking_customer case, to keep the "pick up" high, we need to determine specific agent actions that concretize the customer's intent.

Table 5 shows how mentioning discount-related phrases affects the pick up ratios for rates_customers and booking_customers. From this table, it can be seen that mentioning discount phrases affects the final status of both types of customers. In the rates_customer case, the probability that the booked car will be picked up, $P(\text{pick-up})$ is improved to 0.476 by mentioning discount phrases. This means customers are attracted by offering discounts and this changes their intention from "just checking rate" to "make a reservation here". We found similar trends for the association between mention of value selling phrases and pick up information.

Table 5: Association between mention of discount phrases and pick up information

$Rates\_customer$	Pick up information	
Mention of discount phrases by agents	pick up	not-picked up
yes (21)	10	11
no (16)	3	13

$Booking\_customer$	Pick up information	
Mention of discount phrases by agents	pick up	not picked up
yes (40)	30	10
no (30)	17	13

4.4 Improving Agent Productivity

From the results of the text mining analysis experiment, we derived the following actionable insights:

- There are two types of customers in reservation calls.
  - **Booking_customer** (with strong start) tends to pick up the reserved car.
  - **Rates_customer** (with weak start) tends not to pick up the reserved car.
- In the **rates_customer** case, "pick up" is improved by mentioning discount phrases.

By implementing the actionable insights derived from the analysis in an actual car rental process, we verified improvements in pick up. We divided the 83 agents in the car rental reservation center into two groups. One of them, consisting of 22 agents, was trained based on the insights from the text mining analysis. The remaining 61 agents were not told about these findings. By comparing these two groups over a period of one month we hoped to see how the actionable insights contributed to improving agent performance. As the evaluation metric, we used the pick up ratio - that is the ratio of the number of “pick-ups” to the number of reservations.

Following the training the pick up ratio of the trained agents increased by 4.75%. The average pick up ratio for the remaining agents increased by 2.08%. Before training the ratios of both groups were comparable. The seasonal trends in this industry mean that depending on the month the bookings and pickups may go up or down. We believe this is why the average pick up ratio for the remaining agents also increased. Considering this, it can be estimated that by implementing the actionable insights the pick up ratio for the pilot group was improved by about 2.67%. We confirmed that this difference is meaningful because the p-value of the t-test statistic is 0.0675 and this probability is close to the standard t-test (α=0.05). Seeing this, the contact center trained all of its agents based on the insights from the text mining analysis.

5 Discussion

There has been a lot of work on specific tools for analyzing the conversational data collected at contact centers. These include call type classification for the purpose of categorizing calls (Tang et al., 2003) (Zweig et al., 2006), call routing (Kuo and Lee, 2003) (Haffner et al., 2003), obtaining call log summaries (Douglas et al., 2005), agent assisting and monitoring (Mishne et al., 2005), and building of domain models (Roy and Subramaniam, 2006). Filtering problematic dialogs automatically from an automatic speech recognizer has also been studied (Hastie et al., 2002) (Walker et al., 2002). In contrast to these technologies, in this paper we consider the task of trying to find insights from a collection of complete conversations. In (Nasukawa and Nagano, 2001), such an analysis was attempted for agent-entered call summaries of customer contacts by extracting phrases based on domain-expert-specified viewpoints. In our work we have shown that even for conversational data, which is more complex, we could identify proper viewpoints and prepare expressions for each viewpoint. Call summaries by agents tend to mask the customers’ intention at the start of the call. We get more valuable insights from the text mining analysis of conversational data. For such an analysis of conversational data, our proposed method has an important role. With our method, we find the important segments in the data for doing analyses. Also our analyses are closely linked to the desired outcomes.

In trigger detection, we created a chronologically cumulative data set based on turns. We can also use the segment information such as the “opening” and “enquiries” described in Section 2. We prepared data with segment information manually assigned, made the chronologically cumulative data and applied our trigger detection method. Figure 6 shows the results of $acc(categorizer(D_k))$. The trend in Figure 6 is similar to that in Figure 5. From this result, it is observed that ”opening” and ”offering” segments are trigger segments. Usually, segmentation is not done in advance and to assign such information automatically we need data with labeled segmentation information. The results show that even in the absence of labeled data our trigger detection method identifies the trigger segments. In the experiments in Section 4, we set turns for each chronologically cumulative data by taking into account the pre-defined call flow.

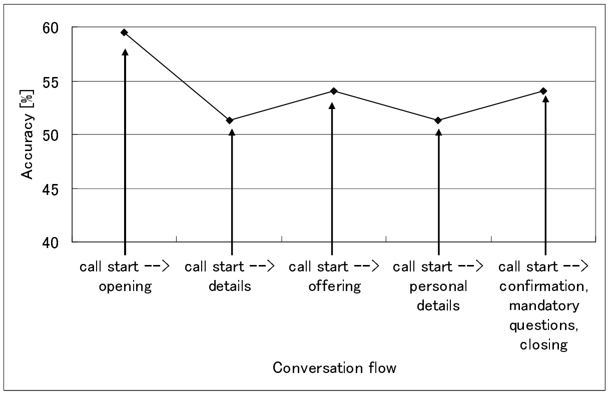

Figure 6: Result of $acc(categorizer(D_k))$ using segment information

In Figure 5 we observe that the accuracy of the categorizer is decreasing even when using increasing parts of the call. Even the accuracy using the complete call is less than using only the first turn. This indicates that the first turn is very informative, but it also indicates that the *features* are not being used judiciously. In a conventional classification task, the number of features are sometimes restricted when constructing a categorizer. It is known that selecting only significant features improves the classification accuracy (Yang and Pedersen, 1997). We used *Information Gain* for selecting features from the document collection. This method selects the most discriminative features between two classes. As expected the classification accuracy improved significantly as we reduced the total number of features from over 2,000 to the range of 100 to 300. Figure 7 shows the changes in accuracy. In the proposed method, we detect trigger segments using the increases and decreases of the classification accuracy. By selecting features, the noisy features are not added in the segments. Decreasing portions, therefore are not observed. In this situation, as a trigger segment, we can detect the portion where the gradient of the accuracy curve increases. Also using feature selection, we find that the classification accuracy is highest when using the entire document, which is expected. However, we notice that the trigger segments obtained with and without feature selection are almost the same.

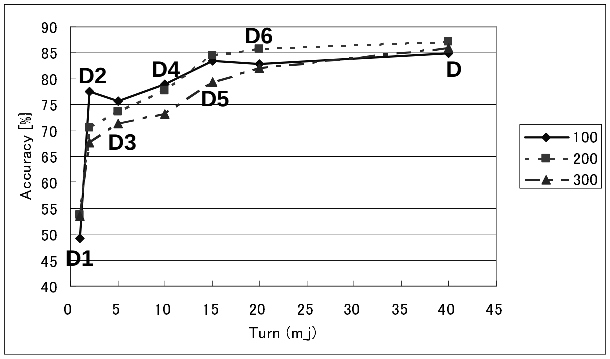

Figure 7: Result of $acc(categorizer(D_k))$ with top 100 to 300 features selected using information gain

In the experiment, we use manually transcribed data. As future work we would like to use the noisy output of an automatic speech recognition system to obtain viewpoints and expressions.

6 Conclusion

In this paper, we have proposed methods for identifying appropriate segments and expressions automatically from the data for user specified difference analysis. We detected the trigger segments using the property that a business-oriented conversation follows a pre-defined flow. After that, we identified the appropriate expressions from each trigger segment. It was found that in a long business-priented conversation there are important segments affecting the outcomes that can not been easily detected by just looking through the conversation, but such segments can be detected by monitoring the changes of the categorization accuracy. For the trigger segment detection, we do not use semantic segment information but only the positional segment information based on the conversational turns. Because our method does not rely on the semantic information in the data, therefore our method can be seen as robust. Through experiments with real conversational data, using identified segments and expressions we were able to define appropriate viewpoints and concepts leading to insights for improving the car rental business process.

Acknowledgment

The authors would like to thank Sreeram Balakrishnan, Raghuram Krishnapuram, Hideo Watanabe, and Koichi Takeda at IBM Research for their support. The authors also appreciate the efforts of Jatin Joy Giri at IBM India in providing domain knowledge about the car rental process and thank him for help in constructing the dictionaries.

Smoothed Bloom filter language models: Tera-Scale LMs on the Cheap

Abstract

A Bloom filter (BF) is a randomised data structure for set membership queries. Its space requirements fall significantly below lossless information-theoretic lower bounds but it produces false positives with some quantifiable probability. Here we present a general framework for deriving smoothed language model probabilities from BFs.

We investigate how a BF containing n-gram statistics can be used as a *direct replacement* for a conventional n-gram model. Recent work has demonstrated that corpus statistics can be stored efficiently within a BF, here we consider how smoothed language model probabilities can be derived efficiently from this randomised representation. Our proposal takes advantage of the one-sided error guarantees of the BF and simple inequalities that hold between related n-gram statistics in order to further reduce the BF storage requirements and the error rate of the derived probabilities. We use these models as replacements for a conventional language model in machine translation experiments.

1 Introduction

Language modelling (LM) is a crucial component in statistical machine translation (SMT). Standard n-gram language models assign probabilities to translation hypotheses in the target language, typically as smoothed trigram models (Chiang, 2005). Although it is well-known that higher-order language models and models trained on additional monolingual corpora can significantly improve translation performance, deploying such language models is not trivial. Increasing the order of an n-gram model can result in an exponential increase in the number of parameters; for the English Gigaword corpus, for instance, there are 300 million distinct trigrams and over 1.2 billion distinct five-grams. Since a language model is potentially queried millions of times per sentence, it should ideally reside locally in memory to avoid time-consuming remote or disk-based lookups.

Against this background, we consider a radically different approach to language modelling. Instead of explicitly storing all distinct n-grams from our corpus, we create an implicit randomised representation of these statistics. This allows us to drastically reduce the space requirements of our models. In this paper, we build on recent work (Talbot and Osborne, 2007) that demonstrated how the *Bloom filter* (Bloom (1970); BF), a space-efficient randomised data structure for representing sets, could be used to store corpus statistics efficiently. Here, we propose a framework for deriving smoothed n-gram models from such structures and show via machine translation experiments that these *smoothed Bloom filter language models* may be used as direct replacements for standard n-gram models in SMT.

The space requirements of a Bloom filter are quite spectacular, falling significantly below information-theoretic error-free lower bounds. This efficiency, however, comes at the price of *false positives*: the filter may erroneously report that an item not in the set is a member. False negatives, on the other hand, will

Proceedings of the 2007 Joint Conference on Empirical Methods in Natural Language Processing and Computational Natural Language Learning, pp. 468–476, Prague, June 2007. ©2007 Association for Computational Linguistics

never occur: the error is said to be *one-sided*. Our framework makes use of the *log-frequency Bloom filter* presented in (Talbot and Osborne, 2007), and described briefly below, to compute smoothed conditional n-gram probabilities on the fly. It takes advantage of the one-sided error guarantees of the Bloom filter and certain inequalities that hold between related n-gram statistics drawn from the same corpus to reduce both the error rate and the computation required in deriving these probabilities.

2 The Bloom filter

In this section, we give a brief overview of the Bloom filter (BF); refer to Broder and Mitzenmacher (2005) for a more in detailed presentation. A BF represents a set $\mathcal{S} = \{x_1, x_2, ..., x_n\}$ with n elements drawn from a universe $\mathcal{U}$ of size N. The structure is attractive when $N \gg n$. The only significant storage used by a BF consists of a bit array of size m. This is initially set to hold zeroes. To train the filter we hash each item in the set k times using distinct hash functions $h_1, h_2, ..., h_k$. Each function is assumed to be independent from each other and to map items in the universe to the range 1 to m uniformly at random. The k bits indexed by the hash values for each item are set to 1; the item is then discarded. Once a bit has been set to 1 it remains set for the lifetime of the filter. Distinct items may not be hashed to k distinct locations in the filter; we ignore collisons. Bits in the filter can, therefore, be *shared* by distinct items allowing significant space savings but introducing a non-zero probability of false positives at test time. There is no way of directly retrieving or ennumerating the items stored in a BF.

At test time we wish to discover whether a given item was a member of the original set. The filter is queried by hashing the test item using the same k hash functions. If all bits referenced by the k hash values are 1 then we *assume* that the item was a member; if any of them are 0 then we *know* it was not. True members are always correctly identified, but a false positive will occur if all k corresponding bits were set by other items during training and the item was not a member of the training set.

The probability of a false postive, f, is clearly the probability that none of k randomly selected bits in the filter are still 0 after training. Letting p be the proportion of bits that are still zero after these n elements have been inserted, this gives,

$$f = (1 - p)^k.$$

As n items have been entered in the filter by hashing each k times, the probability that a bit is still zero is,

$$p^{'} = \left(1 - \frac{1}{m}\right)^{kn} \approx e^{-\frac{kn}{m}}$$

which is the expected value of p. Hence the false positive rate can be approximated as,

$$f = (1 - p)^k \approx (1 - p^{'})^k \approx \left(1 - e^{-\frac{kn}{m}}\right)^k.$$

By taking the derivative we find that the number of functions k^* that minimizes f is,

$$k^* = \ln 2 \cdot \frac{m}{n},$$

which leads to the intuitive result that exactly half the bits in the filter will be set to 1 when the optimal number of hash functions is chosen.

The fundmental difference between a Bloom filter's space requirements and that of any lossless representation of a set is that the former does not depend on the size of the (exponential) universe N from which the set is drawn. A lossless representation scheme (for example, a hash map, trie etc.) must depend on N since it assigns a distinct representation to each possible set drawn from the universe.

3 Language modelling with Bloom filters

Recent work (Talbot and Osborne, 2007) presented a scheme for associating static frequency information with a set of n-grams in a BF efficiently.[1]

3.1 Log-frequency Bloom filter

The efficiency of the scheme for storing n-gram statistics within a BF presented in Talbot and Osborne (2007) relies on the Zipf-like distribution of n-gram frequencies: most events occur an extremely small number of times, while a small number are very frequent. We assume that raw counts are quantised and employ a logarithmic codebook that maps counts, $c(x)$, to quantised counts, $qc(x)$, as follows,

$$qc(x) = 1 + \lfloor \log_b c(x) \rfloor. \quad (1)$$

[1] Note that as described the Bloom filter is *not* an associative data structure and provides only a Boolean function characterising the set that has been stored in it.

Algorithm 1 Training frequency BF

```
Input: $\mathcal{S}_{train}$, $\{h_1, ...h_k\}$ and $\mathcal{BF} = \emptyset$
Output: $\mathcal{BF}$
for all $x \in \mathcal{S}_{train}$ do
    $c(x) \leftarrow$ frequency of $n$-gram $x$ in $\mathcal{S}_{train}$
    $qc(x) \leftarrow$ quantisation of $c(x)$ (Eq. 1)
    for $j = 1$ to $qc(x)$ do
        for $i = 1$ to $k$ do
            $h_i(x) \leftarrow$ hash of event $\{x, j\}$ under $h_i$
            $\mathcal{BF}[h_i(x)] \leftarrow 1$
        end for
    end for
end for
return $\mathcal{BF}$
```

The precision of this codebook decays exponentially with the raw counts and the scale is determined by the base of the logarithm b; we examine the effect of this parameter on our language models in experiments below.

Given the quantised count $qc(x)$ for an n-gram x, the filter is trained by entering composite events consisting of the n-gram appended by an integer counter j that is incremented from 1 to $qc(x)$ into the filter. To retrieve an n-gram's frequency, the n-gram is first appended with a counter set to 1 and hashed under the k functions; if this tests positive, the counter is incremented and the process repeated. The procedure terminates as soon as any of the k hash functions hits a 0 and the previous value of the counter is reported. The one-sided error of the BF and the training scheme ensure that the actual quantised count cannot be larger than this value. As the counts are quantised logarithmically, the counter is usually incremented only a small number of times.

We can then approximate the original frequency of the n-gram by taking its expected value given the quantised count retrieved,

$$E[c(x)|qc(x) = j] = \frac{b^{j-1} + b^j - 1}{2}. \quad (2)$$

These training and testing routines are repeated here as Algorithms 1 and 2 respectively.

As noted in Talbot and Osborne (2007), errors for this log-frequency BF scheme are one-sided: frequencies will never be underestimated. The probability of overestimating an item's frequency decays exponentially with the size of the overestimation error d (i.e. as f^d for $d > 0$) since each erroneous increment corresponds to a single false positive and d such independent events must occur together.

Algorithm 2 Test frequency BF

```
Input: $x$, $MAXQCOUNT$, $\{h_1, ...h_k\}$ and $\mathcal{BF}$
Output: Upper bound on $c(x) \in \mathcal{S}_{train}$
for $j = 1$ to $MAXQCOUNT$ do
    for $i = 1$ to $k$ do
        $h_i(x) \leftarrow$ hash of event $\{x, j\}$ under $h_i$
        if $\mathcal{BF}[h_i(x)] = 0$ then
            return $E[c(x)|qc(x) = j - 1]$ (Eq. 2)
        end if
    end for
end for
```

The efficiency of the log-frequency BF scheme can be understood from an entropy encoding perspective under the distribution over frequencies of n-gram types: the most common frequency (the singleton count) is assigned the shortest code (length k) while rarer frequencies (those for more common n-grams) are assigned increasingly longer codes ($k \times qc(x)$).

3.2 Smoothed BF language models

A standard n-gram language model assigns conditional probabilities to target words given a certain context. In practice, most standard n-gram language models employ some form of interpolation whereby probabilities conditioned on the most specific context consisting usually of the $n - 1$ preceding tokens are combined with more robust estimates based on less specific conditioning events. To compute smoothed language model probabilities, we generally require access to the frequencies of n-grams of length 1 to n in our training corpus. Depending on the smoothing scheme, we may also need auxiliary statistics regarding the number of distinct suffixes for each n-gram (e.g., Witten-Bell and Kneser-Ney smoothing) and the number of distinct prefixes or contexts in which they appear (e.g., Kneser-Ney). We can use a single BF to store these statistics but need to distinguish each type of event (e.g., raw counts, suffix counts, etc.). Here we use a distinct set of k hash functions for each such category.

Our motivation for storing the corpus statistics directly rather than precomputed probabilities is twofold: (i) the efficiency of the scheme described above for storing frequency information together with items in a BF relies on the frequencies having a Zipf-like distribution; while this is definitely true for corpus statistics, it may well not hold for probabilities estimated from them; (ii) as will become apparent below, by using the corpus statistics directly, we will be able to make additional savings in terms of both space and error rate by using simple inequalities that hold for related information drawn consistently from the same corpus; it is not clear whether such bounds can be established for probabilities computed from these statistics.

3.2.1 Proxy items

There is a potential risk of redundancy if we represent related statistics using the log-frequency BF scheme presented in Talbot and Osborne (2007). In particular, we do not need to store information explicitly that is necessarily implied by the presence of another item in the training set, if that item can be identified efficiently at query time when needed. We use the term *proxy item* to refer to items whose presence in the filter implies the existence of another item *and* that can be efficiently queried given the implied item. In using a BF to store corpus statistics for language modelling, for example, we can use the event corresponding to an n-gram and the counter set to 1 as a proxy item for a distinct prefix, suffix or context count of 1 for the same n-gram since (ignoring sentence boundaries) it must have been preceded and followed by at least one distinct type, i.e.,

$$qc(w_1, ..., w_n) \geq 1 \in BF \Rightarrow s(w_1, ..., w_n) \geq 1,$$

where $s(\cdot)$ is the number of the distinct types following this n-gram in the training corpus. We show below that such lower bounds allow us to significantly reduce the memory requirements for a BF language model.

3.2.2 Monotonicity of n-gram event space

The error analysis in Section 2 focused on the false positive rate of a BF; if we deploy a BF within an SMT decoder, however, the actual error rate will also depend on the *a priori* membership probability of items presented to it. The error rate Err is,

$$Err = Pr(x \notin S_{train}|Decoder)f.$$

This implies that, unlike a conventional lossless data structure, the model's accuracy depends on other components in system and how it is queried.

Assuming that statistics are entered consistently from the same corpus, we can take advantage of the monotonicity of the n-gram event space to place upper bounds on the frequencies of events to be retrieved from the filter prior to querying it, thereby reducing the *a priori* probability of a negative and consequently the error rate.

Specifically, since the log-frequency BF scheme will never underestimate an item's frequency, we can apply the following inequality recursively and bound the frequency of an n-gram by that of its least frequent subsequence,

$$c(w_1, ..., w_n) \leq \min\{c(w_1, ..., w_{n-1}), c(w_2, ..., w_n)\}.$$

We use this to reduce the error rate of an interpolated BF language model described below.

3.3 Witten-Bell smoothed BF LM

As an example application of our framework, we now describe a scheme for creating and querying a log-frequency BF to estimate n-gram language model probabilities using Witten-Bell smoothing (Bell et al., 1990). Other smoothing schemes, notably Kneser-Ney, could be described within this framework using additional proxy relations for infix and prefix counts.

In Witten-Bell smoothing, an n-gram's probability is discounted by a factor proportional to the number of times that the $n-1$-gram preceding the current word was observed preceding a novel type in the training corpus. It is defined recursively as,

$$P_{wb}(w_i|w_{i-n+1}^{i-1}) = \lambda_{w_{i-n+1}^{i-1}} P_{ml}(w_i|w_{i-n+1}^{i-1}) \\ + (1-\lambda_{w_{i-n+1}^{i-1}}) P_{wb}(w_i|w_{i-n+2}^{i-1})$$

where λ_x is defined via,

$$1 - \lambda_x = \frac{c(x)}{s(x) + c(x)},$$

and $P_{ml}(\cdot)$ is the maximum likelihood estimator calculated from relative frequencies.

The statistics required to compute the Witten-Bell estimator for the conditional probability of an n-gram consist of the counts of all n-grams of length

1 to n as well as the counts of the number of distinct types following all n-grams of length 1 to $n - 1$. In practice we use the $c(w_1, ..., w_i) = 1$ event as a proxy for $s(w_1, ..., w_i) = 1$ and thereby need not store singleton suffix counts in the filter.

Distinct suffix counts of 2 and above are stored by subtracting this proxy count and converting to the log quantisation scheme described above, i.e.,

$$qs(x) = 1 + \lfloor \log_b(s(x) - 1) \rfloor$$

In testing for a suffix count, we first query the item $c(w_1, ..., w_n) = 1$ as a proxy for $s(w_1, ..., w_n) = 1$ and, if found, query the filter for incrementally larger suffix counts, taking the reconstructed suffix count of an n-gram with a non-zero n-gram count to be the expected value, i.e.,

$$E[s(x)|qs(x) = j \cap j > 0] = 1 + \frac{(b^{j-1} + b^j - 1)}{2}$$

Having created a BF containing these events, the algorithm we use to compute the interpolated WB estimate makes use of the inequalities described above to reduce the *a priori* probability of querying for a negative. In particular, we bound the count of each numerator in the maximum likelihood term by the count of the corresponding denominator and the count of distinct suffixes of an n-gram by its respective token frequency.

Unlike more traditional LM formulations that back-off from the highest-order to lower-order models, our algorithm works up from the lowest-order model. Since the conditioning context increases in specificity at each level, each statistic is bound from above by its corresponding value at the previous less specific level. The bounds are applied by passing them as the parameter $MAXQCOUNT$ to the frequency test routine shown as Algorithm 2. We analyze the effect of applying such bounds on the performance of the model within an SMT decoder in the experiments below. Working upwards from the lower-order models also allows us to truncate the computation before the highest level if the denominator in the maximum likelihood term is found with a zero count at any stage (no higher-order terms can be non-zero given this).

4 Experiments

We conducted a range of experiments to explore the error-space trade-off of using a BF-based model as a replacement for a conventional n-gram model within an SMT system and to assess the benefits of specific features of our framework for deriving language model probabilities from a BF.

4.1 Experimental set-up

All of our experiments use publically available resources. Our main experiments use the French-English section of the *Europarl* (EP) corpus for parallel data and language modelling (Koehn, 2003). Decoding is carried-out using the Moses decoder (Koehn and Hoang, 2007). We hold out 1,000 test sentences and 500 development sentences from the parallel text for evaluation purposes. The parameters for the feature functions used in this log-linear decoder are optimised using minimum error rate (MER) training on our development set unless otherwise stated. All evaluation is in terms of the BLEU score on our test set (Papineni et al., 2002).

Our baseline language models were created using the SRILM toolkit (Stolcke, 2002). We built 3, 4 and 5-gram models from the Europarl corpus using interpolated Witten-Bell smoothing (WB); no n-grams are dropped from these models or any of the BF-LMs. The number of distinct n-gram types in these baseline models as well as their sizes on disk and as compressed by *gzip* are given in Table 1; the *gzip* figures are given as an approximate (and optimistic) lower bound on lossless representations of these models.[2]

The BF-LM models used in these experiments were all created from the same corpora following the scheme outlined above for storing n-gram statistics. Proxy relations were used to reduce the number of items that must be stored in the BF; in addition, unless specified otherwise, we take advantage of the bounds described above that hold between related statistics to avoid presenting known negatives to the filter. The base of the logarithm used in quantization is specified on all figures.

The SRILM and BF-based models are both queried via the same interface in the Moses decoder.

[2] Note, in particular, that *gzip* compressed files do *not* support direct random access as required by in language modelling.

n	Types	Mem.	Gzip'd	BLEU
3	5.9M	174Mb	51Mb	28.54
4	14.1M	477Mb	129Mb	28.99
5	24.2M	924Mb	238Mb	29.07

Table 1: WB-smoothed SRILM baseline models.

We assign a small cache to the BF-LM models (between 1 and 2MBs depending on the order of the model) to store recently retrieved statistics and derived probabilities. Translation takes between 2 to 5 times longer using the BF-LMs as compared to the corresponding SRILM models.

4.2 Machine translation experiments

Our first set of experiments examines the relationship between memory allocated to the BF-LM and translation performance for a 3-gram and a 5-gram WB smoothed BF-LM. In these experiments we use the log-linear weights of the baseline model to avoid variation in translation performance due to differences in the solutions found by MER training: this allows us to focus solely on the quality of each BF-LM's approximation of the baseline. These experiments consider various settings of the base for the logarithm used during quantisation (b in Eq. (1)).

We also analyse these results in terms of the relationships between BLEU score and the underlying error rate of the BF-LM and the number of bits assigned per n-gram in the baseline model.

MER optimised BLEU scores on the test set are then given for a range of BF-LMs.

4.3 Mean squared error experiments

Our second set of experiments focuses on the accuracy with which the BF-LM can reproduce the baseline model's distribution. Unfortunately, perplexity or related information-theoretic quantities are not applicable in this case since the BF-LM is not guaranteed to produce a properly normalised distribution. Instead we evaluate the mean squared error (MSE) between the log-probabilites assigned by the baseline model and by BF-LMs to n-grams in the English portion of our development set; we also consider the relation between MSE and the BLEU score from the experiments above.

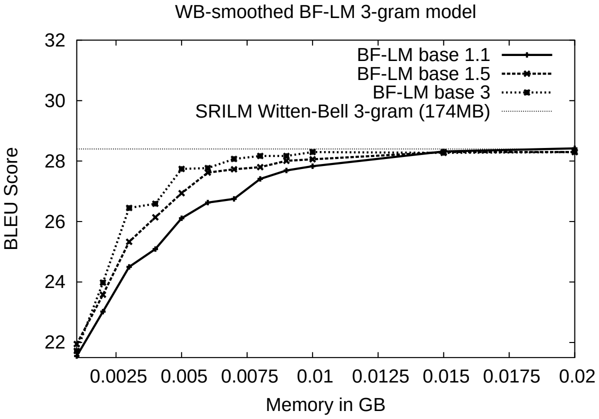

Figure 1: WB-smoothed 3-gram model (Europarl).

4.4 Analysis of BF-LM framework

Our third set of experiments evaluates the impact of the use of upper bounds between related statistics on translation performance. Here the standard model that makes use of these bounds to reduce the *a priori* negative probability is compared to a model that queries the filter in a memoryless fashion.[3]

We then present details of the memory savings obtained by the use of proxy relations for the models used here.

5 Results

5.1 Machine translation experiments

Figures 1 and 2 show the relationship between translation performance as measured by BLEU and the memory assigned to the BF respectively for WB-smoothed 3-gram and 5-gram BF-LMs. There is a clear degradation in translation performance as the memory assigned to the filter is reduced. Models using a higher quantisation base approach their optimal performance faster; this is because these more coarse-grained quantisation schemes store fewer items in the filter and therefore have lower underlying false positive rates for a given amount of memory.

Figure 3 presents these results in terms of the relationship between translation performance and the false positive rate of the underlying BF. We can see that for a given false positive rate, the more coarse-grained quantisation schemes (e.g., base 3) perform

[3] In both cases we apply 'sanity check' bounds to ensure that none of the ratios in the WB formula (Eq. 3) are greater than 1.

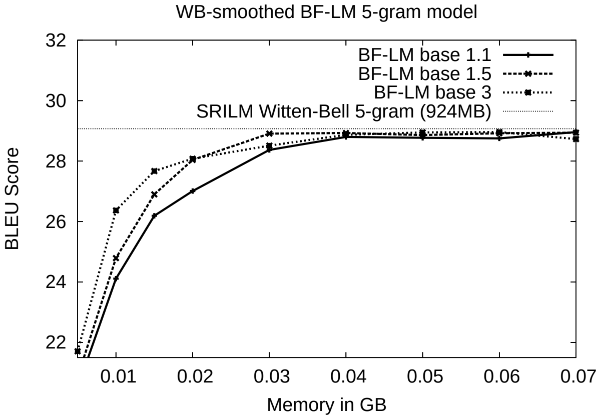

Figure 2: WB-smoothed 5-gram model (Europarl).

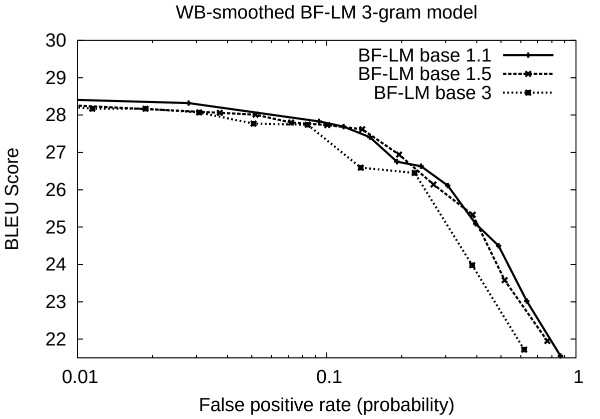

Figure 3: False positive rate vs. BLEU .

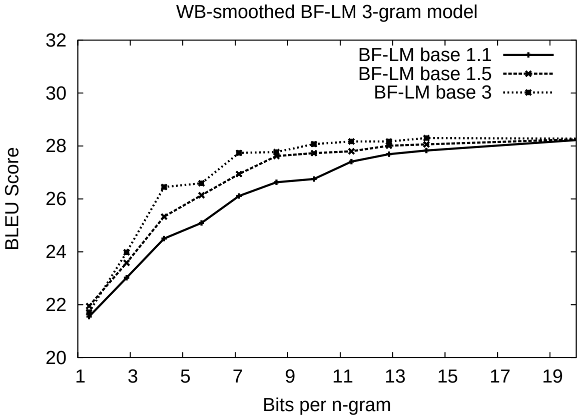

Figure 4: Bits per n-gram vs. BLEU.

n	Memory	Bits / n-gram	base	BLEU
3	10MB	14 bits	1.5	28.33
3	10MB	14 bits	2.0	28.47
4	20MB	12 bits	1.5	28.63
4	20MB	12 bits	2.0	28.63
5	40MB	14 bits	1.5	28.53
5	40MB	14 bits	2.0	28.72
5	50MB	17 bits	1.5	29.31
5	50MB	17 bits	2.0	28.67

Table 2: MERT optimised WB-smoothed BF-LMS.

worse than the more fine-grained schemes.[4]

Figure 4 presents the relationship in terms of the number of bits per n-gram in the baseline model. This suggests that between 10 and 15 bits is sufficient for the BF-LM to approximate the baseline model. This is a reduction of a factor of between 16 and 24 on the plain model and of between 4 and 7 on *gzip* compressed model.

The results of a selection of BF-LM models with decoder weights optimised using MER training are given in Table 2; these show that the models perform consistently close to the baseline models that they approximate.

5.2 Mean squared error experiments

Figure 5 shows the relationship between memory assigned to the BF-LMs and the mean squared error (MSE) of log-probabilities that these models assign to the development set compared to those assigned by the baseline model. This shows clearly that the more fine-grained quantisation scheme (e.g. base 1.1) can reach a lower MSE but also that the more coarse-grained schemes (e.g., base 3) approach their minimum error faster.

Figure 6 shows the relationship between MSE between the BF-LM and the baseline model and BLEU. The MSE appears to be a good predictor of BLEU score across all quantisation schemes. This suggests that it may be a useful tool for optimising BF-LM parameters without the need to run the decoder assuming a target (lossless) LM can be built and queried for a small test set on disk. An MSE of below 0.05 appears necessary to achieve translation performance matching the baseline model here.

5.3 Analysis of BF-LM framework

We refer to (Talbot and Osborne, 2007) for empirical results establishing the performance of the log-frequency BF-LM: overestimation errors occur with

[4] Note that in this case the base 3 scheme will use approximately two-thirds the amount of memory required by the base 1.5 scheme.

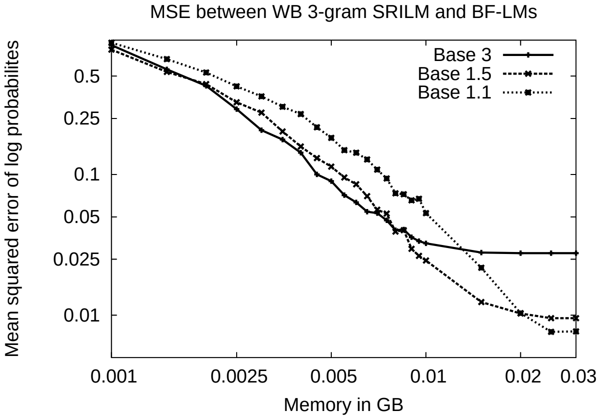

Figure 5: MSE between SRILM and BF-LMs

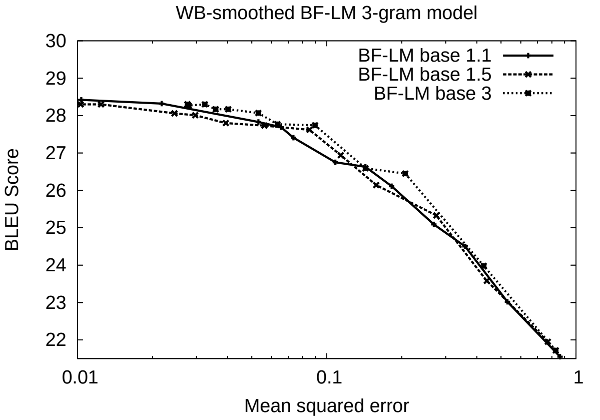

Figure 6: MSE vs. BLEU for WB 3-gram BF-LMs

a probability that decays exponentially in the size of the overestimation error.

Figure 7 shows the effect of applying upper bounds to reduce the *a priori* probability of presenting a negative event to the filter in our interpolation algorithm for computing WB-smoothed probabilities. The application of upper bounds improves translation performance particularly when the amount of memory assigned to the filter is limited. Since both filters have the same underlying false positive rate (they are identical), we can conclude that this improvement in performance is due to a reduction in the number of negatives that are presented to the filter and hence errors.

Table 3 shows the amount of memory saved by the use of proxy items to avoid storing singleton suffix counts for the Witten-Bell smoothing scheme. The savings are given as ratios over the amount of memory needed to store the statistics without proxy items. These models have the same underlying false positive rate (0.05) and quantisation base (2). Similar savings may be anticipated when applying this framework to infix and prefix counts for Kneser-Ney smoothing.

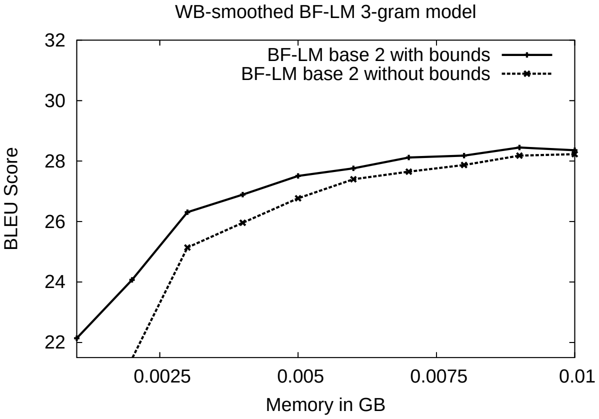

Figure 7: Effect of upper bounds on BLEU

n-gram order	Proxy space saving
3	0.885
4	0.783
5	0.708

Table 3: Space savings via proxy items .

6 Related Work

Previous work aimed at reducing the size of n-gram language models has focused primarily on quantisation schemes (Whitaker and Raj, 2001) and pruning (Stolcke, 1998). The impact of the former seems limited given that storage for the n-gram types themselves will generally be far greater than that needed for the actual probabilities of the model. Pruning on the other hand could be used in conjunction with the framework proposed here. This holds also for compression schemes based on clustering such as (Goodman and Gao, 2000). Our approach, however, avoids the significant computational costs involved in the creation of such models.

Other schemes for dealing with large language models include per-sentence filtering of the model or its distribution over a cluster. The former requires time-consuming adaptation of the model for each sentence in the test set while the latter incurs significant overheads for remote calls during decoding. Our framework could, however, be used to complement either of these approaches.

7 Conclusions and Future Work

We have proposed a framework for computing smoothed language model probabilities efficiently from a randomised representation of corpus statistics provided by a Bloom filter. We have demonstrated that models derived within this framework can be used as direct replacements for equivalent conventional language models with significant reductions in memory requirements. Our empirical analysis has also demonstrated that by taking advantage of the one-sided error guarantees of the BF and simple inequalities that hold between related n-gram statistics we are able to further reduce the BF storage requirements and the effective error rate of the derived probabilities.

We are currently implementing Kneser-Ney smoothing within the proposed framework. We hope the present work will, together with Talbot and Osborne (2007), establish the Bloom filter as a practical alternative to conventional associative data structures used in computational linguistics. The framework presented here shows that with some consideration for its workings, the randomised nature of the Bloom filter need not be a significant impediment to is use in applications.

Abstract

We present results that show that incorporating lexical and structural semantic information is effective for word sense disambiguation. We evaluated the method by using precise information from a large treebank and an ontology automatically created from dictionary sentences. Exploiting rich semantic and structural information improves precision 2–3%. The most gains are seen with verbs, with an improvement of 5.7% over a model using only bag of words and n-gram features.

1 Introduction

Recently, significant improvements have been made in combining symbolic and statistical approaches to various natural language processing tasks. In parsing, for example, symbolic grammars are being combined with stochastic models (Riezler et al., 2002; Oepen et al., 2002; Malouf and van Noord, 2004). Statistical techniques have also been shown to be useful for word sense disambiguation (Stevenson, 2003). However, to date, there have been few combinations of sense information together with symbolic grammars and statistical models. Klein and Manning (2003) show that much of the gain in statistical parsing using lexicalized models comes from the use of a small set of function words. Features based on general relations provide little improvement, presumably because the data is too sparse: in the Penn treebank normally used to train and test statistical parsers *stocks* and *skyrocket* never appear together. They note that this should motivate the use of similarity and/or class based approaches: the superordinate concepts *capital* ($\supset$ *stocks*) and *move upward* ($\supset$ *sky rocket*) frequently appear together. However, there has been little success in this area to date. For example, Xiong et al. (2005) use semantic knowledge to parse Chinese, but gain only a marginal improvement. Focusing on WSD, Stevenson (2003) and others have shown that the use of syntactic information (predicate-argument relations) improve the quality of word sense disambiguation (WSD). McCarthy and Carroll (2003) have shown the effectiveness of the selectional preference information for WSD. However, there is still little work on combining WSD and parse selection.

We hypothesize that one of the reasons for the lack of success is that there has been no resource annotated with both syntactic (or structural semantic information) and lexical semantic information. For English, there is the SemCor corpus (Fellbaum, 1998) which is annotated with parse trees and WordNet senses, but it is fairly small, and does not explicitly include any structural semantic information. Therefore, we decided to construct and use a treebank with both syntactic information (e.g. HPSG parses) and lexical semantic information (e.g. sense tags): the Hinoki treebank (Bond et al., 2004). This can be used to train word sense disambiguation and parse ranking models using both syntactic and lexical semantic features. In this paper, we discuss only word sense disambiguation. Parse ranking is discussed in Fujita et al. (2007).

2 The Hinoki Corpus

The Hinoki corpus consists of the Lexeed Semantic Database of Japanese (Kasahara et al., 2004) and corpora annotated with syntactic and semantic infor-

mation.

2.1 Lexeed

Lexeed is a database built from on a dictionary, which defines word senses used in the Hinoki corpus and has around 49,000 dictionary definition sentences and 46,000 example sentences which are syntactically and semantically annotated. Lexeed consists of all words with a familiarity greater than or equal to five on a scale of one to seven. This gives a fundamental vocabulary of 28,000 words, divided into 46,347 different senses. Each sense has a definition sentence and example sentence written using only these 28,000 familiar words (and some function words). Many senses have more than one sentence in the definition: there are 75,000 defining sentences in all.

A (simplified) example of the entry for 運転手 *untenshu* "chauffeur" is given in Figure 1. Each word contains the word itself, its part of speech (POS) and lexical type(s) in the grammar, and the familiarity score. Each sense then contains definition and example sentences, links to other senses in the lexicon (such as hypernym), and links to other resources, such as the Goi-Taikei (Ikehara et al., 1997) and WordNet (Fellbaum, 1998). Each content word in the definition and example sentences is annotated with sense tags from the same lexicon.

2.2 Lexical Semantics Annotation

The lexical semantic annotation uses the sense inventory from Lexeed. All words in the fundamental vocabulary are tagged with their sense. For example, the word 大きい *ookii* "big" (in *ookiku naru* "grow up") is tagged as sense 5 in the example sentence (Figure 1), with the meaning "elder, older".

Each word was annotated by five annotators. We use the majority choice in case of disagreements (Tanaka et al., 2006). Inter-annotator agreements among the five annotators range from 78.7% to 83.3%: the lowest agreement is for the Lexeed definition sentences and the highest is for Kyoto corpus (newspaper text). These agreements reflect the difficulties in disambiguating word sense over each corpus and can be considered as the upper bound of precision for WSD.

Table 1 shows the distribution of word senses according to the word familiarity in Lexeed.

		Poly-		#Mono-
Fam	#Words	semous	#WS	semous(%)
6.5 -	368	182	4.0	186 (50.5)
6.0 -	4,445	1,902	3.4	2,543 (57.2)
5.5 -	9,814	3,502	2.7	6,312 (64.3)
5.0 -	11,430	3,457	2.5	7,973 (69.8)

Table 1: Word Senses in Lexeed

2.3 Ontology

The Hinoki corpus comes with an ontology semi-automatically constructed from the parse results of definitions in Lexeed (Nichols and Bond, 2005). The ontology includes more than 80 thousand relationships between word senses, e.g. synonym, hypernym, abbreviation, etc. The hypernym relation for 運転手 *untenshu* "chauffeur" is shown in Figure 1. Hypernym or synonym relations exist for almost all content words.

2.4 Thesaurus

As part of the ontology verification, all nominal and most verbal word senses in Lexeed were linked to semantic classes in the Japanese thesaurus, Nihongo Goi-Taikei (Ikehara et al., 1997). These were then hand verified. Goi-Taikei has about 400,000 words including proper nouns, most nouns are classified into about 2,700 semantic classes. These semantic classes are arranged in a hierarchical structure (11 levels). The Goi-Taikei Semantic Class for 運転手 *untenshu* "chauffeur" is shown in Figure 1: $\langle$`C292:driver`$\rangle$ at level 9 which is subordinate to $\langle$`C4:person`$\rangle$.

2.5 Syntactic and Structural Semantics Annotation

Syntactic annotation is done by selecting the best parse (or parses) from the full analyses derived by a broad-coverage precision grammar. The grammar is an HPSG implementation (JACY: Siegel and Bender, 2002), which provides a high level of detail, marking not only dependency and constituent structure but also detailed semantic relations. As the grammar is based on a monostratal theory of grammar (HPSG: Pollard and Sag, 1994) it is possible to simultaneously annotate syntactic and semantic structure without overburdening the annotator. Using a grammar enforces treebank consistency — all sentences annotated are guaranteed to have well-

INDEX	運転手 *untenshu*	
POS	noun	
LEX-TYPE	`noun-lex`	
FAMILIARITY	6.2 [1–7] ($\geq$ 5)	
SENSE 1	DEFINITION	電車$_1$ や 自動車$_1$ を 運転$_1$ する 人$_4$ a person who drives trains and cars
	EXAMPLE	大きく$_5$ なったら電車$_1$ の運転手$_1$ に成る$_6$ のが夢$_3$ です。 I dream of growing up and becoming a train driver
	HYPERNYM	人$_4$ *hito* “person”
	SEM. CLASS	⟨`292:driver`⟩ (⊂ ⟨`4:person`⟩)
	WORDNET	*motorman*$_1$

Figure 1: Dictionary Entry for 運転手$_1$ *untenshu* “chauffeur”

formed parses. The flip side to this is that any sentences which the parser cannot parse remain unannotated, at least unless we were to fall back on full manual mark-up of their analyses. The actual annotation process uses the same tools as the Redwoods treebank of English (Oepen et al., 2002).

There were 4 parses for the definition sentence shown in Figure 1. The correct parse, shown as a phrase structure tree, is shown in Figure 2. The two sources of ambiguity are the conjunction and the relative clause. The parser also allows the conjunction to join to 電車 *densha* and 人 *hito*. In Japanese, relative clauses can have gapped and non-gapped readings. In the gapped reading (selected here), 人 *hito* is the subject of 運転 *unten* “drive”. In the non-gapped reading there is some underspecified relation between the thing and the verb phrase. This is similar to the difference in the two readings of *the day he knew* in English: “the day that he knew about” (gapped) vs “the day on which he knew (something)” (non-gapped). Such semantic ambiguity is resolved by selecting the correct derivation tree that includes the applied rules in building the tree.

The parse results can be automatically given by the HPSG parser PET (Callmeier, 2000) with the Japanese grammar JACY. The current parse ranking model has an accuracy of 70%: the correct tree is ranked first 70% of the time (for Lexeed definition sentences) (Fujita et al., 2007).

The full parse is an HPSG sign, containing both syntactic and semantic information. A view of the semantic information is given in Figure 3[1].

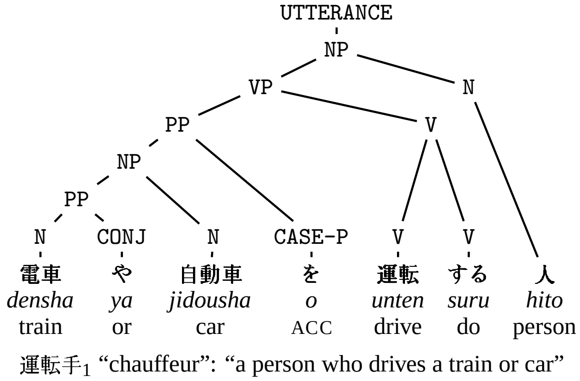

Figure 2: Syntactic View of the Definition of 運転手$_1$ *untenshu* “chauffeur”

The semantic view shows some ambiguity has been resolved that is not visible in the purely syntactic view.

The semantic view can be further simplified into a dependency representation, further abstracting away from quantification, as shown in Figure 4. One of the advantages of the HPSG sign is that it contains all this information, making it possible to extract the particular view needed. In order to make linking to other resources (such as the sense annotation) easier, predicates are labeled with pointers back to their position in the original surface string. For example, the predicate `densha_n_1` links to the surface characters between positions 0 and 3: 電車.

[1] The specific meaning representation language used in JACY is Minimal Recursion Semantics (Copestake et al., 2005).

3 Task

We define the task in this paper as “allocating the word sense tags for all content words included in Lexeed as headwords, in each input sentence”. This task is a kind of all-words task, however, a unique point is that we focus on fundamental vocabulary (basic words) in Lexeed and ignore other words. We use Lexeed as the sense inventory. There are two problems in resolving the task: how to build the model and how to assign the word sense by using the model for disambiguating the senses. We describe the word sense selection model we use in section 4 and the method of word sense assignment in section 5.

4 Word Sense Selection Model

All content words (i.e. basic words) in Lexeed are classified into six groups by part-of-speech: noun, verb, verbal noun, adjective, adverb, others. We treat the first five groups as targets of disambiguating senses. We build five words sense models corresponding to these groups. A model contains senses for various words, however, features for a word are discriminated from those for other words so that the senses irrelevant to a target word are not selected. For example, an n-gram feature following a target word “has-a-tail” for *dog* is distinct from that for *cat*.

In the remainder of this section, we describe the features used in the word sense disambiguation. First we used simple n-gram collocations, then a bag of words of all words occurring in the sentence. This was then enhanced by using ontological information and predicate argument relations.

4.1 Word Collocations

Word collocations (WORD-Col) are basic and effective cues for WSD. They can be modelled by n-gram and bag of words features, which are easily extracted from a corpus. We used all unigrams, bigrams and trigrams which precede and follow the target words (N-gram) and all content words in the sentences where the target words occur (BOW).

The first column numbers the feature template corresponding to each example.

4.2 Semantic Features

We use the semantic information (sense tags and ontologies) in two ways. One is to enhance the collocations and the other is to enhance dependency relations.

4.2.1 Semantic Collocations

Word surface features like N-gram and BOW inevitably suffer from data sparseness, therefore, we generalize them to more abstract words or concepts and also consider words having the same meanings. We used the ontology described in Section 2.3 to get hypernyms and synonyms and the Goi-Taikei thesaurus to abstract the words to the semantic classes. The superordinate classes at level 3, 4 and 5 are also added in addition to the original semantic class. For example, 電車 *densha* "train" and 自動車 *jidousha* "automobile" are both generalized to the semantic class ⟨C988:land vehicle⟩ (level 7). The superordinate classes are also used: ⟨C706:inanimate⟩ (level 3), ⟨C760:artifact⟩ (level 4) and ⟨C986:vehicle⟩ (level 5).

4.2.2 Semantic Dependencies

The semantic dependency features are based on a predicate and its arguments taken from the elementary dependencies. For example, consider the semantic dependency representation for *densha ya jidousha-wo unten suru hito* "a person who drives a train or car" given in Figure 4. The predicate *unten* "drive", has two arguments: ARG1 *hito* "person" and ARG2 *ya* "or". The coordinate conjunction is expanded out into its children, giving ARG2 *densha* "train" and *jidousha* "automobile".

D322	⟨PRED:C2003, ARG1:人$_4$, ARG2:電車$_1$⟩

Table 3: Example semantic features extracted from the dependency tree in Figure 4. The first column numbers the feature template corresponding to each example.

From these, we produce several features, a sample of them are shown in Table 3. One has all arguments and their labels (D11). We also produce various back offs, for example the predicate with only one argument at a time (D1-D3). Each combination of predicate and its related argument(s) becomes a feature.

For the next class of features, we used the sense information from the corpus combined with the semantic classes in the dictionary to replace each predicate by its disambiguated sense, its hypernym, its synonym (if any) and its semantic class. The semantic classes for 電車$_1$ and 自動車$_1$ are both ⟨`988:land vehicle`⟩, while 運転$_1$ is ⟨`2003:motion`⟩ and 人$_4$ is ⟨`4:human`⟩. We also expand 自動車$_1$ into its synonym モーターカー$_1$ *mōtākā* "motor car".

The semantic class features provide a semantic smoothing, as words are binned into the 2,700 classes. The hypernym/synonym features provide even more smoothing. Both have the effect of making more training data available for the disambiguator.

4.3 Domain

Domain information is a simple and sometimes strong cue for disambiguating the target words (Gliozzo et al., 2005). For instance, the sense of the word "*record*" is likey to be different in the musical context, which is recalled by domain-specific words like "*orchestra*", "*guitar*", than in the sporting context. We use 12 domain categories like "culture/art", "sport", etc. which are similar to ones used in directory search web sites. About 6,000 words are automatically classified into one of 12 domain categories by distributions in web sites (Hashimoto and Kurohashi, 2007) and 10% of them are manually checked. Polysemous words which belong to multiple domains and neutral words are not classified into any domain.

5 Search Algorithm

The conditional probability of the word sense for each word is given by the word sense selection model described in Section 4. In the initial state, some of the semantic features, e.g. semantic collocations (SEM-Col) and word sense extensions for semantic dependencies (SEM-Dep) are not available, since no word senses for polysemous words have been determined. It is not practical to count all combinations of word senses for target words, therefore, we first try to decide the sense for that word which is most plausible among all the ambiguous words, then, disambiguate the next word by using the sense.

We use the beam search algorithm, which is similar to that used for decoder in statistical machine translation (Watanabe, 2004), for finding the plausible combination of word sense tags.

The algorithm is described as follows. For a polysemous word set in an input sentence $\{w_1,\ldots,w_n\}$, t_{w_ik} is the k-th word sense of word w_i, W is a set having words to be disambiguated, T is a list of resolved word senses. A search node N is defined as $[W,T]$ and a score of a node N, $s(N)$ is defined as the probability that the word sense set T occurs in the context. The beam search can be done as follows (beam width is b):

1. Create an initial node $N_0 = [T_0,W_0]$ ($T_0 = \{\}$, $W_0 = \{\}$) and insert the node into an initial queue Q_0.

2. For each node N in the queue Q, do the following steps.
   - For each w_i $(\in W)$, create W'_i by picking out w_i from W
   - Create new lists $T'_1,\ldots,T'_l$ by adding one of word sense candidates $t_{w_i1},\ldots,t_{w_il}$ for w_i to T
   - Create new nodes $[W'_i,T'_0],\ldots,[W'_i,T'_l]$ and insert them into the queue Q'

3. Sort the nodes in Q' by the score $s(N)$

4. If the top node W in the queue Q' is empty, adopt T as the combination of word senses and terminate. Otherwise, pick out the top b nodes from Q' and insert them into new queue Q, then go back to 2

6 Evaluation

We trained and tested on the Lexeed Dictionary Definition (LXD-DEF) and Example sections (LXD-EX) of the Hinoki corpus (Bond et al., 2007). These have about 75,000 definition and 46,000 example sentences respectively. Some 54,000 and 36,000 sentences of them are treebanked, i.e., they have the syntactic trees and structural semantic information. We used these sentences with the complete information and selected 1,000 sentences out of each sentence class as test sets (LXD-DEF$_{\text{test}}$, LXD-EX$_{\text{test}}$), and the remainder is combined and used as a training set (LXD-ALL). We also tested 1,000 sentences from the Kyoto Corpus of newspaper text (KYOTO$_{\text{test}}$). These sentences have between 3.4 (LXD-EX$_{\text{test}}$) – 5.2 (KYOTO$_{\text{test}}$) polysemous words per sentence on average.

We use a *maximum entropy / minimum divergence* (MEMD) modeler to train the word sense selection model. We use the open-source Maximun Entropy Modeling Toolkit[2] for training, determining best-performing convergence thresholds and prior sizes experimentally. The models for five different POSs were trained with each training sets: the base model is word collocation model (WORD-Col), and the semantic models built by semantic collocation (SEM-Col), semantic dependency (SEM-Dep) or domain with WORD-Col (+SEM-Col, +SEM-Dep and +DOMAIN).

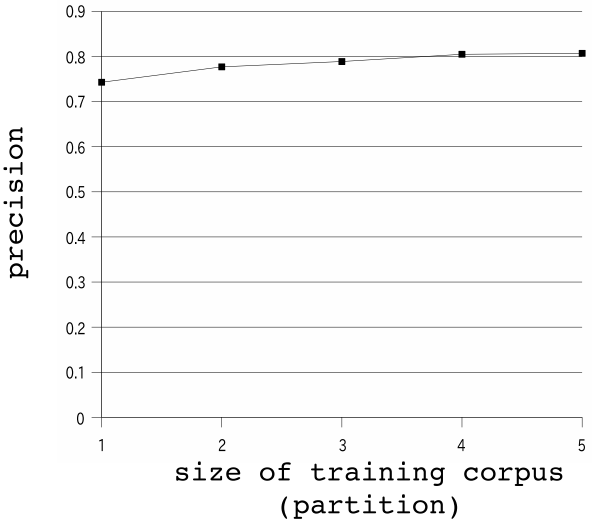

Figure 5: Learning Curve

7 Results and Discussion

Table 4 shows the precision as the results of the word sense disambiguation on the combination of LXD-DEF and LXD-EX (LXD-ALL). The baseline method selects the senses occurring most frequently in the training corpus. Each row indicates the results using the baseline, word collocation (WORD-Col), the combinations of WORD-Col and one of the semantic features (+SEM-Col, +SEM-Dep and +DOMAIN), e.g, +SEM-Col gives the results using WORD-Col and SEM-Col, and all features (FULL).

There are significant improvements over the baseline and the other results on all corpora. Basic word collocation features (WORD-Col) give a vast improvement. Extending this by using the ontological information (+SEM-Col) gives a further improvement over the WORD-Col. Adding the predicate-argument relationships (+SEM-Dep) improves the results even more.

Table 6 shows the statistics of the target corpora. The best result of LXD-DEF$_{test}$ (80.7%) surpasses the inter-annotator agreement (78.7%) in building the Hinoki Sensebank. However, there is a wide gap between the best results of KYOTO$_{test}$ (60.4%) and the inter-annotator agreement (83.3%), this suggests other information such as the semantic classes for named entities (including proper nouns and multiword expressions (MWE)) and broader contexts are required. However, a model built on dictionary sentences lacks these features. Even, so there is some improvement.

The domain features (+DOMAIN) give small contribution to the precision, since only intra-sentence context is counted in this experiment. Unfortunately dictiory definition and example sentences do not really have a useful context. We expect broader context should make the domain features more effective for the newspaper text (e.g. as in Stevenson (2003)),

Table 5 shows comparison of results of different POSs. The semantic features (+SEM-Col and +SEM-Dep) are particularly effective for verb and also give moderate improvements on the results of the other POSs.

Figure 5 shows the precisions of LXD-DEF$_{test}$ in changing the size of a training corpus, which is divided into five partitions. The precision is saturated in using four partitions (264,000 tokens).

These results of the dictionary sentences are close to the best published results for the SENSEVAL-2 task (79.3% by Murata et al. (2003) using a combination of simple Bayes learners). However, we are using a different sense inventory (Lexeed not Iwanami (Nishio et al., 1994)) and testing over a different corpus, so the results are not directly comparable. In future work, we will test over SENSEVAL-2 data so that we can compare directly.

None of the SENSEVAL-2 systems used ontological information, despite the fact that the dictionary definition sentences were made available, and there are several algorithms describing how to extract such information from MRDs (Tsurumaru

et al., 1991; Wilkes et al., 1996; Nichols et al., 2005). We hypothesize that this is partly due to the way the task is presented: there was not enough time to extract and debug an ontology as well as build a disambiguation system, and there was no ontology distributed. The CRL system (Murata et al., 2003) used a syntactic dependency parser as one source of features (KNP: Kurohashi and Nagao (2003)), removing it decreased performance by around 0.6%.

8 Conclusions

We used the Hinoki corpus to test the importance of lexical and structural information in word sense disambiguation. We found that basic n-gram features and collocations provided a great deal of useful information, but that better results could be gained by using ontological information and semantic dependencies.

Abstract

We consider the impact Active Learning (AL) has on effective and efficient text corpus annotation, and report on reduction rates for annotation efforts ranging up until 72%. We also address the issue whether a corpus annotated by means of AL – using a particular classifier and a particular feature set – can be re-used to train classifiers different from the ones employed by AL, supplying alternative feature sets as well. We, finally, report on our experience with the AL paradigm under real-world conditions, i.e., the annotation of large-scale document corpora for the life sciences.

1 Introduction

The annotation of corpora has become a crucial prerequisite for NLP utilities which rely on (semi-) supervised machine learning (ML) techniques. While stability, by and large, has been reached for tagsets up until the syntax layer, semantic annotations in terms of (named) entities, semantic roles, propositions, events, etc. reveal a high degree of variability due to the inherent domain-dependence of the underlying tagsets. This diversity fuels a continuous need for creating semantic annotation data anew.

Accordingly, annotation activities will persist and even increase in number as HLT is expanding on various technical and scientific domains (e.g., the life sciences) outside the classical general-language newspaper genre. Since the provision of annotations is a costly, labor-intensive and error-prone process the amount of work and time this activity requires should be minimized to the extent that corpus data could still be used to effectively train ML-based NLP components on them. The approach we advocate does exactly this and yields reduction gains (compared with standard procedures) ranging between 48% to 72%, without seriously sacrificing annotation quality.

Various techniques to minimize the necessary amount of annotated training material have already been investigated. In co-training (Blum and Mitchell, 1998), e.g., from a small initial set of labeled data multiple learners mutually provide new training material for each other by labeling unseen examples. Pierce and Cardie (2001) have shown, however, that for tasks which require large numbers of labeled examples – such as most NLP tasks – co-training might be inadequate because it tends to generate noisy data. Furthermore, a well compiled initial training set is a crucial prerequisite for successful co-training. As another alternative for minimizing annotation work, active learning (AL) is based on the idea to let the learner have control over the examples to be manually labeled so as to optimize the prediction accuracy. Accordingly, AL aims at selecting those examples with high utility for the model.

AL (as well as semi-supervised methods) is typically considered as a learning protocol, i.e., to train a particular classifier. In contrast, we here propose to employ AL as a corpus annotation method. A corpus built on these premises must, however, still be reusable in a flexible way so that, e.g., training with modified or improved classifiers is feasible and reasonable on AL-generated corpora. Baldridge and Osborne (2004) have already argued that this is a highly critical requirement because the examples selected by AL are tuned to one particular classifier. The second major contribution of this paper ad-

Proceedings of the 2007 Joint Conference on Empirical Methods in Natural Language Processing and Computational Natural Language Learning, pp. 486–495, Prague, June 2007. ©2007 Association for Computational Linguistics

dresses this issue and provides empirical evidence that corpora built with one type of classifier (based on Maximum Entropy) can reasonably be reused by another, methodologically related type of classifier (based on Conditional Random Fields) without requiring changes of the corpus data. We also show that feature sets being used for training classifiers can be enhanced without invalidating corpus annotations generated on the basis of AL and, hence, with a poorer feature set.

2 Related Work

There are mainly two methodological strands of AL research, *viz.* optimization approaches which aim at selecting those examples that optimize some (algorithm-dependent) objective function, such as prediction variance (Cohn et al., 1996), and heuristic methods with uncertainty sampling (Lewis and Catlett, 1994) and query-by-committee (QBC) (Seung et al., 1992) just to name the most prominent ones. AL has already been applied to several NLP tasks, such as document classification (Schohn and Cohn, 2000), POS tagging (Engelson and Dagan, 1996), chunking (Ngai and Yarowsky, 2000), statistical parsing (Thompson et al., 1999; Hwa, 2000), and information extraction (Lewis and Catlett, 1994; Thompson et al., 1999).

In a more recent study, Shen et al. (2004) consider AL for entity recognition based on Support Vector Machines. Here, the informativeness of an example is estimated by the distance to the hyperplane of the currently learned SVM. It is assumed that an example which lies close to the hyperplane has high chances to have an effect on training. This approach is essentially limited to the SVM learning scheme as it solely relies on SVM-internal selection criteria.

Hachey et al. (2005) propose a committee-based AL approach where the committee's classifiers constitute multiple views on the data by employing different feature subsets. The authors focus on (possible) negative side effects of AL on the annotations. They argue that AL annotations are cognitively more difficult to deal with for the annotators (because of the increased complexity of the selected sentences). Hence, lower annotation quality and higher per-sentence annotation times might be a concern.

There are controversial findings on the reusability of data annotated by means of AL for the problem of parse tree selection. Whereas Hwa (2001) reports positive results, Baldridge and Osborne (2004) argue that AL based on uncertainty sampling may face serious performance degradation when labeled data is reused for training a classifier different from the one employed during AL. For committee-based AL, however, there is a lack of work on reusability. Our experiments of committee-based AL for entity recognition, however, reveal that for this task at least, reusability can be guaranteed to a very large extent.

3 AL for Corpus Annotation - Requirements for Practical Use

AL frameworks for real-world corpus annotation should meet the following requirements:

fast selection time cycles — AL-based corpus annotation is an interactive process in which b sentences are selected by the AL engine for human annotation. Once the annotated data is supplied, the AL engine retrains its underlying classifier(s) on *all* available annotations and then re-classifies all unseen corpus items. After that the most informative (i.e., deviant) b sentences from the set of newly classified data are selected for the next iteration round. In this approach the time needed to select the next examples (which is the idle time of the human annotators) has to be kept at an acceptable limit of a few minutes only. There are various AL strategies which – although they yield theoretically near-optimal sample selection – turn out to be actually impractible for real-world use because of excessively high computation times (cf. Cohn et al. (1996)). Thus, AL-based annotation should be based on a computationally tractable and task-wise feasible and acceptable selection strategy (even if this might imply a suboptimal reduction of annotation costs).

reusability — The examples AL selects for manual annotation are dependent on the model being used, up to a certain extent (Baldridge and Osborne, 2004). During annotation time, however, the best model might not be known and model tuning (especially the choice of features) is typically performed once a training corpus is available. Hence, from a practical point of view, the resulting corpus should be reusable with modified classifiers as well.

adaptive stopping criterion — An explicit and adaptive stopping criterion which is sensitive towards the already achieved level of quality of the annotated corpus is clearly preferred over stopping after an *a priori* fixed number of annotation iterations.

If these requirements, especially the first and the second one, cannot be guaranteed for a specific annotation task one should refrain from using AL. The efficiency of AL-driven annotation (in terms of the time needed to compile high quality training material) might be worse compared to the annotation of randomly (or subjectively) selected examples.

4 Framework for AL-based Named Entity Annotation

For named entity recognition (NER), each change of the application domain requires a more or less profound change of the types of semantic categories (tags) being used for corpus annotation. Hence, one may encounter a lack of training material for various relevant (sub)domains. Once this data is available, however, one might want to modify the features of the final classifier with respect to the specific entity types. Thus, a corpus annotated by means of AL has to provide the flexibility to modify the features of the final classifier.

To meet the requirements from above under the constraints of a real-world annotation task, we decided for QBC-based AL, a *heuristic* AL approach, which is computationally less complex and resource-greedy than *objective function* AL methods (the latter explicitly quantify the differences between the current and an ideal classifier in terms of some objective function). Accordingly, we ruled out uncertainty sampling, another heuristic AL approach, because it was shown before that QBC is more efficient and robust (Freund et al., 1997).

QBC is based on the idea to select those examples for manual annotation on which a committee of classifiers disagree most in their predictions (Engelson and Dagan, 1996). A committee consists of a number of k classifiers of the same type (same learning algorithm, parameters, and features) but trained on different subsets of the training data. QBC-based AL is also iterative. In each AL round the committee's k classifiers are trained on the already annotated data C, then a pool of unannotated data P is predicted with each classifier resulting in n automatically labeled versions of P. These are then compared according to their labels. Those with the highest variance are selected for manual annotation.

4.1 Selection Strategy

In each iteration, a batch of b examples is selected for manual annotation. The informativeness of an example is estimated in terms of the *disagreement*, i.e., the uncertainty among the committee's classifiers on classifying a particular example. This is measured by the *vote entropy* (Engelson and Dagan, 1996), i.e., the entropy of the distribution of classifications assigned to an example by the classifiers. Vote entropy is defined on the token level t as:

$$D_{tok}(t) := -\frac{1}{\log k} \sum_{l_i} \frac{V(l_i,t)}{k} \log \frac{V(l_i,t)}{k}$$

where $\frac{V(l_i,t)}{k}$ is the ratio of k classifiers where the label l_i is assigned to a token t. As (named) entities often span more than a single text token we consider complete sentences as a reasonable example size unit[1] for AL and calculate the disagreement of a sentence D_{sent} as the mean vote entropy of its single tokens. Since the vote entropy is minimal when all classifiers agree in their vote, sentences with high disagreement are preferred for manual annotation. With informed decisions of human annotators made available, the potential for future disagreement of the classifier committee on conflicting instances should decrease. Thus, each AL iteration selects the b sentences with the highest disagreement to focus on the most controversial decision problems.

Besides informativeness, additional criteria can be envisaged for the selection of examples, e.g., *di-*

[1] Sentence-level examples are but one conceivable grain size – lower grains (such as clauses or phrases) as well as higher grains (e.g., paragraphs or abstracts) are equally possible, with different implications for the AL process.

feature class	description
orthographical	based on regular expressions (e.g. *HasDash*, *IsGreek*, ...), token transformation rule: capital letters replaced by “A”, lowercase letters by “a”, digits by “0”, etc. (e.g., *IL2 → AA0*, *have → aaaa*)
lexical and morphological	prefix and suffix of length 3, stemmed version of each token
syntactic	the token’s part-of-speech tag
contextual	features of neighboring tokens

Table 1: Features used for AL

versity of a batch and *representativeness* of the respective example (to avoid outliers) (Shen et al., 2004). We experimented with these more sophisticated selection strategies but preliminary experiments did not reveal any significant improvement of the AL performance. Engelson and Dagan (1996) confirm this observation that, in general, different (and even more refined) selection methods still yield similar results. Moreover, strategies incorporating more selection criteria often require more parameters to be set. However, proper parametrization is hard to achieve in real-world applications. Using disagreement exclusively for selection requires only one parameter, *viz.* the batch size b, to be specified.

4.2 Classifier and Features

For our AL framework we decided to employ a Maximum Entropy (ME) classifier (Berger et al., 1996). We employ a rich set of features (see Table 1) which are general enough to be used in most (sub)domains for entity recognition. We intentionally avoided using features such as semantic triggers or external dictionary look-ups because they depend a lot on the specific subdomain and entity types being used. However, one might add them to fin- tune the final classifier, if needed. ME classifiers outperform their generative counterparts (e.g., Naïve Bayesian classifiers) because they can easily handle overlapping, probably dependent features which might be contained in rich feature sets. We also favored an ME classifier over an SVM one because the latter is computationally much more complex on rich feature sets and multiple classes and is thus not so well suited for an interactive process like AL.

It has been shown that *Conditional Random Fields* (CRF) (Lafferty et al., 2001) achieve higher performance on many NLP tasks, such as NER, but on the other hand they are computionally more complex than an ME classifier making them also impractical for the interactive AL process. Thus, in our committee we employ ME classifiers to meet requirement 1 (fast selection time cycles). However, in the end we want to use the annotated corpora to train a CRF and will thus examine the reusability of such an ME-annotated AL corpus for CRFs (cf. Subsection 5.2).

4.3 Stopping Criterion

A question hardly addressed up until now is when to actually terminate the AL process. Usually, it gets stopped when the supervized learning performance of the specific classifier is achieved. The problem with such an approach is, however, that in practice one does not know the performance level which could possibly be achieved on an unannotated corpus.

An apparent way to monitor the progress of the annotation process is to periodically (e.g., after each AL iteration) train a classifier on the data annotated so far and evaluate it against some randomly selected gold standard. When the relative performance growth of each AL iteration falls below a certain threshold this might be a good reason to stop the annotation. Though this is probably the most reliable way, it is impractical for many scenarios since assembling and manually annotating a representative gold standard may already be quite a laborious task. Thus, a measure from which we can *predict* the development of the learning curve would be beneficial.

One way to achieve this goal is to monitor the rate of disagreement among the different classifiers after each iteration. This rate will descend as the classifiers get more and more robust in their predictions on unseen data. Thus, an average disagreement approaching zero can be interpreted as an indication that additional annotations will not render any further improvement. In our experiments, we will show that this is a valid stopping criterion, indeed.

5 Experiments and Results

For our experiments, we specified the following three parameters: the batch size b (i.e., the number of sentences to be selected for each AL iteration), the size and composition of the initial training set, and the number of k classifiers in a committee. The smaller the batch size, the higher the AL performance turns out to be. In the special case of batch size of $b = 1$ only that example with the highest disagreement is selected. This is certainly impractical since after each AL iteration a new committee of classifiers has to be trained causing unwarranted annotation idle time. We found $b = 20$ to be a good compromise between the annotators' idle time and AL performance. The initial training set also contains 20 sentences which are randomly selected though. Our committee consists of $k = 3$ classifiers, which is a good trade-off between computational complexity and diversity. Although the AL iterations were performed on the sentence level, we report on the number of annotated tokens. Since sentences may considerably vary in their length the number of tokens constitutes a better measure for annotation costs.

We ran our experiments on two common entity-annotated corpora from two different domains (see Table 2). From the general-language newspaper domain, we used the English data set of the CoNLL-2003 shared task (Tjong Kim Sang and De Meulder, 2003). It consists of a collection of newswire articles from the Reuters Corpus,[2] which comes annotated with three entity types: *persons*, *locations*, and *organizations*. From the sublanguage biology domain we used the oncology part of the PENNBIOIE corpus which consists of some 1150 PubMed abstracts. Originally, this corpus contains gene, variation event, and malignancy entity annotations. Manual annotation after each AL round was simulated by moving the selected sentences from the pool of unannotated sentences P to the training corpus T. For our simulations, we built two subcorpora by filtering out entity annotations: the PENNBIOIE gene corpus (PBgene), including the three gene entity subtypes *generic*, *protein*, and *rna*, and the PENNBIOIE variation events corpus (PBvar) corpus including the variation entity subtypes *type*, *event*, *location*, *state-altered*, *state-generic*, and *state-original*. We split all three corpora into two subsets, *viz.* AL simulation data and gold standard data on which we evaluate[3] a classifier in terms of f-score trained on the annotated corpus after each AL iteration (learning curve). As far as the CoNLL corpus is concerned, we have used CoNLL's training set for AL and CoNLL's test set as gold standard. As for PBgene and PBvar, we randomly split the corpora into 90% for AL and 10% as gold standard.

corpus	data set	sentences	tokens
CONLL 3 entities	AL	14,040	203,617
	Gold	3,453	46,435

	Gold	1,114	27,563

Table 2: Corpora used in the Experiments

In the following experiments we will refer to the classifiers used in the AL committee as *selectors*, and the classifier used for evaluation as the *tester*.

5.1 Efficiency of AL and the Applicability of the Stopping Criterion

In a first series of experiments, we evaluated whether AL-based annotations can significantly reduce the human effort compared to the standard annotation procedure where sentences are selected randomly (or subjectively). We also show that disagreement is an accurate stopping criterion. As described in Section 4.2, we here employed a committee of ME classifiers for AL; a CRF was used as tester for both the AL and the random selection. Figures 1, 2, and 3 depict the learning curves for AL selection and random selection (upper two curves) and the respective disagreement curves (lower curve). The random selection curves contained in these plots are averaged over three random selection runs.

With AL, we get a maximum f-score of ≈ 84.5% on the CoNLL corpus after about 118,000 tokens. At about the same number of tokens the disagreement curve drops down to values of around $D_{sent} = 0$. Comparing AL and random selection, an f-score of ≈ 84% is reached after 86,000 and 165,000 tokens, respectively, which means a reduction of annotation costs of about 48%. On PBgene, the effect of AL is comparable: a maximum value of 83.5% f-score is reached first after about 124,000 tokens, a data point where hardly any disagreement between the committee's classifiers occurs. For, e.g., an f-score of

[2] `http://trec.nist.gov/`

[3] We use a strict evaluation criterion which only counts exact matches as true positives because annotations having incorrect boundaries are insufficient for manual corpus annotation.

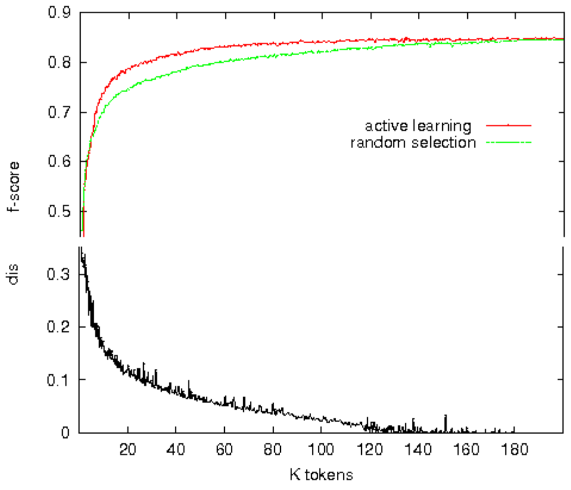

Figure 1: CoNLL Corpus: Learning/Disagreement Curves

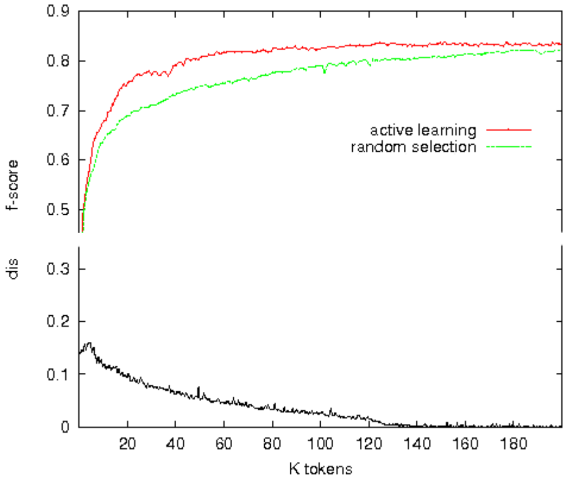

Figure 2: PBgene Corpus: Learning/Disagreement Curves

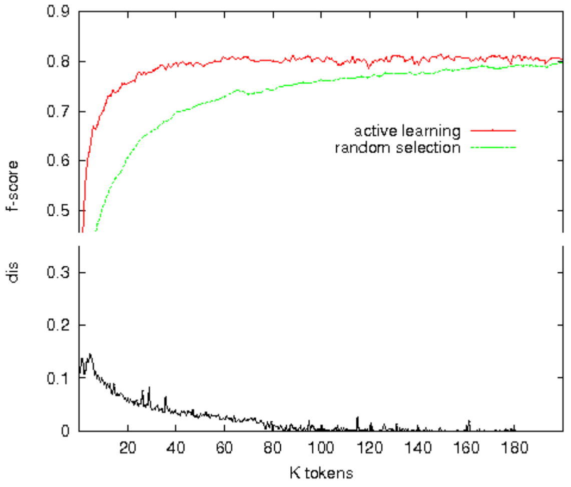

Figure 3: PBvar Corpus: Learning/Disagreement Curves

corpus	selection	F	tokens	reduction
CoNLL	random	84.0	165,000	
	AL	84.0	86,000	≈ 48%
PBgene	random	83.0	101,000	
	AL	83.0	213,000	≈ 53%
PBvar	random	80.0	56,000	
	AL	80.0	200,000	≈ 72%

Table 3: Reduction of Annotation Costs Achieved with AL-based Annotation

83%, the annotation effort can be reduced by about 53% using AL. On PBvar, an f-score of about 80% is reached after ≈ 56,000 tokens when using AL selection, while 200,000 tokens are needed with random selection. For this task, AL reduces the annotation effort by of 72%. Here, the disagreement curve approaches values of zero after approximately 80,000 tokens. At about this point the learning curve reaches its maximum of about 81% f-score. Table 3 summarizes the reduction of annotation costs achieved on all three corpora.

Comparing both PennBioIE simulations, obviously, the reduction of annotation costs through AL is much higher for the variation type entities than for the gene entities. We hypothesize this to be mainly due to incomparable entity densities. Whereas the gene entities are quite frequent (about 1.3 per sentence on average), the variation entities are rather sparse (0.62 per sentence on average) making it an ideal playground for AL-based annotation. Our experiments also reveal that disagreement approaching values of zero is a valid stopping criterion. This is, under all circumstances, definitely the point when AL-based annotation *should* stop because then all classifiers of the committee vote consistently. Any further selection – even though AL selection is used – is then, actually, a *random* selection. If, due to reasons whatsoever, further annotations are wanted, a direct switch to random selection is advisable because this is computationally less expensive than AL-based selection.

5.2 Reusability

To evaluate whether the proposed AL framework for named entity annotation allows for flexible re-use of the annotated data, we performed experiments where we varied both the learning algorithms and the features of the selectors.

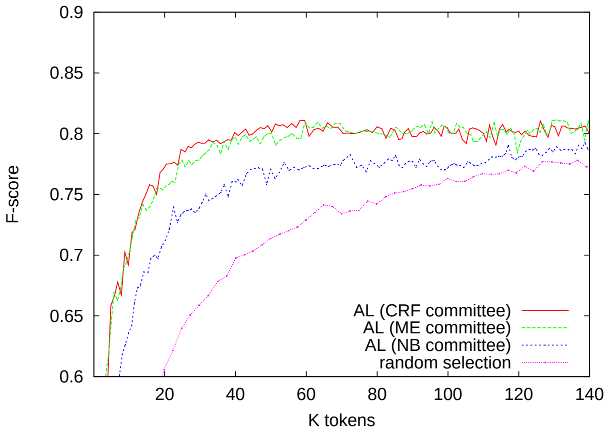

Figure 4: Algorithm Flexibility on PBvar

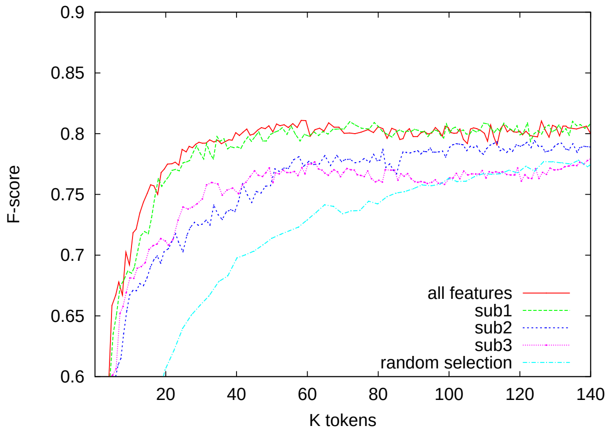

Figure 6: Feature Flexibility on PBvar

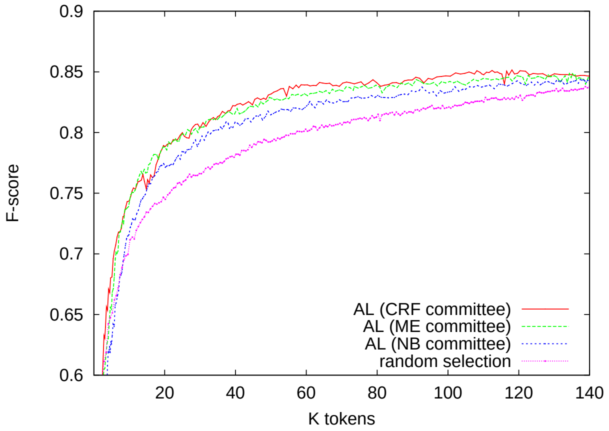

Figure 5: AlgorithmFflexibility on CoNLL

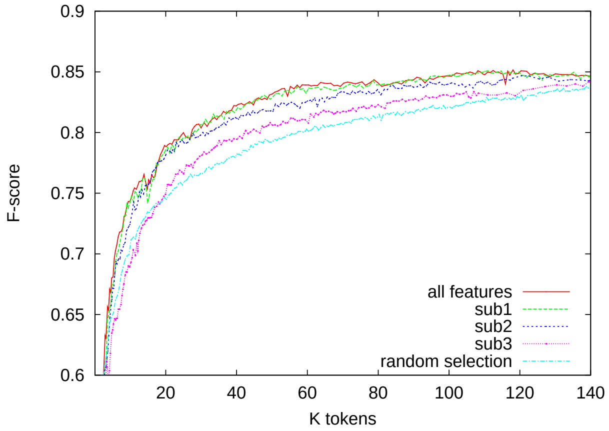

Figure 7: Feature Flexibility on ConLL

First, we analyzed the effect of different probabilistic classifiers as selectors on the resulting learning curve of the CRF tester. Figures 4 and 5 show the learning curves on our original ME committee, a CRF committee, and also a committee of Naïve Bayes (NB) classifiers. It is not surprising that self-reuse (CRF selectors and CRF tester) yields the best results. Switching from CRF selectors to ME selectors has almost no negative effect. Even with a committee of NB selectors (an ML approach which is essentially less well suited for the NER task), AL-based selection is still substantially more efficient than random selection on both corpora. This shows that our approach to use the less complex ME classifiers for the AL selection process has the positive effect of fast selection cycle times at almost no costs. This is especially interesting as the performance of an ME classifier trained in supervized manner on the complete corpus is significantly worse (several percentage points of f-measure) than a CRF. That means, even though an ME classifier is less well suited as the final classifier, it works well as a selector for CRFs.[4]

Second, we ran experiments on selectors with only some features and our CRF tester with all features (cf. Table 1). Feature subset 1 (*sub1*) contains all but the syntactic features. In the second subset (*sub2*), also morphological and lexical features are missing. The third set (*sub3*) only contains orthographical features. We ran an AL simulation for

[4] We have also conducted experiments where we varied the learning algorithms of the tester (we experimented with NB, ME, MEMM, and CRFs) – with comparable results. In a realistic scenario, however, on would rather choose a CRF as final tester over, e.g., a NB.

each feature subset with a committee of CRF selectors.[5] Figures 6 and 7 show the various learning curves. Here we see that a corpus that was produced with AL on *sub1* can easily be re-used by a tester with little more features. This is probably the most realistic scenario: the core features are kept and only a few specific features (e.g., POS, a dictionary look-up, chunk information, etc.) are added. When adding substantially more features to the tester than were available during AL time, the respective learning curves drop down towards the learning curve for random selection. But even with a selector which has only orthographical features and a tester with many more features – which is actually quite an extreme example and a rather unrealistic scenario for a real-world application – AL is more efficient than random selection. However, the limits of reusability are taking shape: on PBvar, the AL selection with *sub3* converges with the random selection curve after about 100,000 tokens.

5.3 Findings with Real AL Annotation

We currently perform AL entity mention annotations for an information extraction project in the biomedical subdomain of immunogenetics. For this purpose, we retrieved about 200,000 abstracts (≈ 2,000,000 sentences) as our document pool of unlabeled examples from PUBMED. By means of random subsampling, only about 40,000 sentences are considered in each round of AL selection. To regularly monitor classifier performance, we also perform gold standard (GS) annotations on 250 randomly chosen abstracts (≈ 2,200 sentences). In all our annotations of different entity types so far, we found AL learning curves similar to the ones reported in our simulation experiments, with classifier performance levelling off at around 75% - 85% f-score (depending on the entity type).

Our annotations also reveal that AL is especially beneficial when entity mentions are very sparse. Figure 8 shows the cumulated entity density on AL and gold standard annotations of cytokine receptors (specialized proteins for which we annotated six different entity subtypes) – very sparse entity types with less than one entity mention per PUBMED abstract on the average. As can be seen, after 2,000 sentences the entity density in our AL corpus is almost 15 times higher than in our GS corpus. Such a dense corpus may be more appropriate for classifier training than a sparse one yielded by random or sequential annotations, which may just contain lots of negative training examples. We have observed comparable effects with other entity types, too, and thus conclude that the sparser entity mentions of a specific type are in texts, the more beneficial AL-based annotation is. We report on other aspects of AL for real annotation projects in Tomanek et al. (2007).

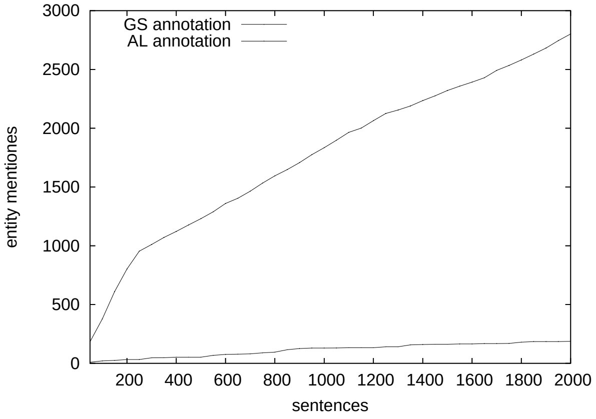

Figure 8: Cumulated Entity Density on AL and GS Annotations of Cytokine Receptors

6 Discussion and Conclusions

We have shown, for the annotation of (named) entities, that AL is well-suited to speed up annotation work under realistic conditions. In our simulations we yielded gains (in the number of tokens) up to 72%. We collected evidence that an average disagreement approaching zero may serve as an adaptive stopping criterion for AL-driven annotation and that a corpus compiled by means of QBC-based AL is to a large extent reusable by modified classifiers.

These findings stand in contrast to those supplied by Baldridge and Osborne (2004) who focused on parse selection. Their research indicates that AL on selectors with different learning algorithms and feature sets then used by the tester can easily get worse than random selection. They conclude that it might not be be advisable to employ AL in environments where the final classifier is not very stable.

Our evidence leads us to a re-assessment of AL-

[5] Here, we employed CRF instead of ME selectors to isolate the effect of feature re-usability.

based annotations. First, we employed a committee-based (QBC) while Baldridge and Osborne performed uncertainty sampling AL. Committee-based approaches calculate the uncertainty on an example in a more implicit way, i.e., by the disagreement among the committee's classifiers. With uncertainty sampling, however, the labeling uncertainty of one classifier is considered directly. In future work we will directly compare QBC and uncertainty sampling with respect to data reusability. Second, whereas Baldridge and Osborne employed AL on a scoring or ranking problem we focused on classification problems. Further research is needed to investigate whether the problem class (classification with a fixed and moderate number of classes vs. ranking large numbers of possible candidates) is responsible for limited data reusability.

On the basis of our experiments we stipulate that the proposed AL approach might be applicable with comparable results to a wider range of corpus annotation tasks, which otherwise would require substantially larger amounts of annotation efforts.

Antecedent Selection Techniques for High-Recall Coreference Resolution

Yannick Versley
versley@sfs.uni-tuebingen.de

Universität Tübingen

Abstract

We investigate methods to improve the recall in coreference resolution by also trying to resolve those definite descriptions where no earlier mention of the referent shares the same lexical head (coreferent bridging). The problem, which is notably harder than identifying coreference relations among mentions which have the same lexical head, has been tackled with several rather different approaches, and we attempt to provide a meaningful classification along with a quantitative comparison. Based on the different merits of the methods, we discuss possibilities to improve them and show how they can be effectively combined.

1 Introduction

Coreference resolution, the task of grouping mentions in a text that refer to the same referent in the real world, has been shown to be beneficial for a number of higher-level tasks such as information extraction (McCarthy and Lehnert, 1995), question answering (Morton, 2000) and summarisation (Steinberger et al., 2005).

While the resolution of pronominal anaphora and tracking of named entities is possible with good accuracy, the resolution of definite NPs (having a common noun as their head) is usually limited to the cases that Vieira and Poesio (2000) call direct coreference, where both coreferent mentions have the same head. The other cases, called coreferent bridging by Vieira and Poesio[1], are notably harder because the number of potential candidates is much larger when it is no longer possible to rely on surface similarity.

To overcome the limit of recall that is encountered when only relying on surface features, newer systems for coreference resolutions (Daumé III and Marcu, 2005; Ponzetto and Strube, 2006; Versley, 2006; Ng, 2007, *inter alia*) use lexical semantic information as an indication for semantic compatibility in the absence of head equality. Most current systems integrate the identification of discourse-new definites (i.e., cases like *"the sun"* or *"the man that Ben met yesterday"*, which are definite, but not anaphoric) with the antecedent selection proper, which implies that the gain obtained for new features is dependent on the feature's usefulness both in finding semantically related mentions and for the use in detecting discourse-new definites.

One goal of this paper is to provide a better understanding of these information sources by comparing proposed (and partly new) approaches for resolving coreferent bridging by separately considering the task of antecedent selection (i.e., presupposing that discourse-new markables have been identified beforehand). Although state of the art methods for modular discourse-new detection (Uryupina, 2003; Poesio et al., 2005) do not achieve near-perfect accuracy for discourse-new detection, the results we give for antecedent selection represent an upper bound on recall and precision for the full coreference task, and we think that this upper bound will be useful for

[1] Because bridging (in the sense of Clark, 1975, or Asher and Lascarides, 1998) is a much broader concept, the term 'coreferent bridging' is potentially confusing, as many cases are examples of perfectly well-behaved anaphoric definite noun phrases. Because we want to emphasise the important difference to the more easily resolved cases of same-head coreference, we will stick with 'coreferent bridging' as the only term that has been established for this in the literature.

Proceedings of the 2007 Joint Conference on Empirical Methods in Natural Language Processing and Computational Natural Language Learning, pp. 496–505, Prague, June 2007. ©2007 Association for Computational Linguistics

the design of features in both systems using a modular approach, such as (Poesio et al., 2005), where the decision on discourse-newness is taken beforehand, and those that integrate discourse-new classification with the actual resolution of coreferent bridging cases. In contrast to earlier investigations (Markert and Nissim, 2005; Garera and Yarowsky, 2006), we provide a more extensive overview on features and also discuss properties that influence their combinability.

Several approaches have been proposed for the treatment of coreferent bridging. Poesio et al. (1997) use WordNet, looking for a synonymy or hypernymy relation (additionally, for coordinate sisters in WordNet). The system of Cardie and Wagstaff (1999) uses the node distance in WordNet (with an upper limit of 4) as one component in the distance measure that guides their clustering algorithm. Harabagiu et al. (2001) use paths through Wordnet, using not only synonym and is-a relations, but also parts, morphological derivations, gloss texts and polysemy, which are weighted with a measure based on the relation types and number of path elements. Other approaches use large corpora to get an indication for bridging relations: Poesio et al. (1998) use a general word association metric based on common terms occuring in a fixed-width window, Gasperin and Vieira (2004) use syntactic contexts of words in a large corpus to induce a semantic similarity measure (similar to the one introduced by Lin, 1998), and then use lists of the n nouns that are (globally) most similar to a given noun. Markert and Nissim (2005) mine the World Wide Web for shallow patterns like "*China* and other *countries*", indicating an is-a relationship. Finally, Garera and Yarowsky (2006) propose an association-based approach using nouns that occur in a 2-sentence window before a definite description that has no same-head antecedent.

1.1 Lexical vs. Referential Relations

One important property of these information sources is the kind of lexical relations that they detect. The lexical relations that we expect in coreferent bridging cases are:

- instance: The antecedent is an instance of the concept denoted by the anaphor
  Corsica . . . the island

- synonymy: The antecedent and the anaphor are synonyms
  the automobile . . . the car

- hyperonymy: The anaphor is a strict generalisation of the antecedent
  the murderer . . . the man

- near-synonymy: The anaphor and antecedent are semantically related but not synonyms in the strict sense
  the CD . . . the album

Of course, not all cases of coreferent bridging realise such a lexical relation, as sometimes the anaphor takes up information introduced elsewhere than in the lexical noun phrase head (Peter was found dead in his flat . . . the deceased), or the coreference relation is forced by the discourse structure, without the items being lexically related.

As an illustrating example, in

(1) John walked towards [1 the house].

(2) a. [1 The building] was illuminated.
b. [1 The manor] was guarded by dogs.
c. [2 The door] was open.

Typical cases of coreference include cases like 1,2a (hypernym) or 1,2b (compatible but non-synonymous term). The discourse in 1,2c is an example of associative bridging between the NP *"the door"* and its antecedent to *"the house"*; it is inferred that the door must be part of the house mentioned earlier (since doors are typically part of a house), which is *not* compatible with coreferent bridging, but is also ranked highly by association measures.

While hypernym relations (as found by hypernym lookup in WordNet, or patterns indicating such relations in unannotated texts) are usually a strong indicator of coreference, they can only cover some of the cases, while the near-synonymous cases are left undiscovered. Similarity and association measures can help for the cases of near-synonymy. However, while similarity measures (such as WordNet distance or Lin's similarity metric) only detect cases of semantic similarity, association measures (such as the ones used by Poesio et al., or by Garera and Yarowsky) also find cases of associative bridg-

Table 1: Similarity and association measures: most similar items

ing like 1a,b; the result of this can be seen in table (2): while the similarity measures (Lin98, RFF) list substitutable terms (which behave like synonyms in many contexts), the association measures (Garera and Yarowsky's TheY measure, Padó and Lapata's association measure) also find non-compatible associations such as *country–capital* or *drug–treatment*, which is why they are commonly called *relation-free*. For the purpose of coreference resolution, however we do *not* want to resolve *"the door"* to the antecedent *"the house"* as the two descriptions do not corefer, and it may be useful to filter out non-similar associations.

1.2 Information Sources

Different resources may be differently suited for the recognition of the various relations. Generally, it would be expected that using a wordnet is the best solution if we are interested in an isa-like relation between two words. On the other hand, wordnets usually have limited coverage both in terms of lexical items and in terms of relations encoded (as their construction is necessarily labor-intensive), and – as Markert and Nissim remark – they do not (and arguably should not) contain context-dependent relations that do not hold generally but only in some rather specific context, for example *steel* being anaphorically described as a *commodity* in a financial text. Context-dependent relations, Markert and Nissim argue, can be found using shallow patterns (for example, *steel and other commodities*), since a use in such a context would mean that the idiosyncratic conceptual relation holds in that context. Wordnets also have usually have poor (or non-existant) coverage of named entities, which are especially relevant for instance relations; this kind of instance relations can often be found in large text corpora. The high-precision patterns that Markert and Nissim use only occur infrequently, but the approach using shallow patterns allows to perform the search of the World Wide Web, which somewhat alleviates the sparse data problem.

While some near-synonyms can be found by looking at the distance in a wordnet, they may be far apart from each other because of ontological modeling decisions, or lexical items not covered by the wordnet. Similarity and association measures can provide greater coverage for these near-synonym relations.

The measures both of Lin (1998) and of Padó and Lapata (2003, 2007) are distributional methods; for each word, they create a distribution of the contexts they occur in, and similarity between two words is calculated as the similarity of these distributions.[2] The difference in these two methods is the representation of the contexts. While Lin uses contexts that are expected to determine semantic preferences (like being in the direct object position of one verb), Padó and Lapata only use the co-occuring words, weighted by syntax-based distance. For example, in

(3) Peter $\overset{subj}{\rightarrow}$ likes $\overset{dobj}{\leftarrow}$ ice-cream.

Lin's approach would yield $\uparrow subj{:}\texttt{like}$ for `Peter` and $\uparrow dobj{:}\texttt{like}$ for `ice-cream`, while Padó and Lapata's approach would yield the contexts `like` (with a weight of 1.0) and `ice-cream` (with a weight of 0.5) for `Peter`. As a consequence, Padó and Lapata's measure is more robust against data sparseness but also finds related non-similar terms (which are ultimately unwanted for coreference resolution). Padó and Lapata show their dependency-based measure to perform better in a word sense disambiguation task than the measure of Lund et al. (1995), on which Poesio et al. (1998) based their experiments and which is based on the surface distance of words.
